Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Kumar & Clark's Clinical Medicine eighth edition can be fully accessed online via www.studentconsult.com. Follow the instructions on the inside cover to access full text and illustrations, as well as additional features (listed below and online under the 'extras' tab). These include 30 short chapters written by members of our prestigious International Advisory Board. You will also be entitled to one year's free online access to Goldman's Cecil Medicine 24th edition (2704 pages of major medical reference work).

ONLINE CHAPTERS

Editor: Professor Janaka de Silva

- Arsenic poisoning *Dr A K Kundu*
- Brucellosis *Professor S S Fedail*
- Cholera *Professor K N Viswanathan*
- Dengue fever *Professor R Sood*
- Diarrhoeas including amoebiasis *Professor S A Azer*
- Fluorosis *Professor F S Hough*
- Heat stroke and heat stress *Professor S A Azer*
- HIV in resource-limited settings *Professor M Mendelson and Professor G Maartens*
- HIV nephropathy *Dr N Wearne*
- HIV-associated Immune Reconstitution Inflammatory Syndrome (IRIS) *Professor G Meintjes*
- IgA nephropathy *Professor K N Lai*
- Infections caused by Rickettsiae, Orientiae and Coxiella *Dr R Premaratna*
- Leprosy *Professor S A Kamath*
- Leptospirosis *Professor K N Viswanathan*
- Liver transplantation *Dr J T Wells and Professor M R Lucey*
- Malaria *Professor S A Kamath and Professor NR de Silva*
- Neurology of toxins and envenoming *Dr U K Ranawaka*
- Non-communicable diseases in sub-Saharan Africa *Dr N Ntusi*
- Pesticide and plant poisoning *Professor J de Silva*
- Pyogenic meningitis *Dr S Shafqat and Dr A Zaidi*
- Rabies *Professor K N Viswanathan*
- Rheumatic fever *Professor K N Viswanathan*
- Rift Valley fever *Professor O. Khalafallah, Dr A A K Jebriel, Dr M El Sadig, Dr M Mirghani, Professor S S Fedail*
- Severe acute respiratory syndrome (SARS) *Professor K N Lai*
- Snake bite *Professor Dr CA Gnanathanan, R Sheriff and Professor P Agrawal*
- Soil-transmitted helminths *Professor NR de Silva*
- Thrombotic thrombocytopenic purpura (TTP) associated with HIV *Professor V J Louw*
- Tropical sprue *Professor S A Azer*
- Vaccination for adults *Professor R Dewan*
- Vitamin B12 and folic acid deficiency *Professor V J Louw*

INTERACTIVE SURFACE ANATOMY

From Drake et al: *Gray's Anatomy for Students*

Over 40 interactive animations covering the seven body regions, demonstrating major anatomical features, surface landmarks and other palpable structures. We are grateful to the authors of *Gray's Anatomy for Students* for the opportunity to provide Kumar & Clark readers with the benefits of this unique interactive learning tool.

Back

- How to identify specific vertebral spinous processes
- Visualizing the inferior ends of the spinal cord and subarachnoid space

Thorax

- How to count ribs
- Surface anatomy of the breast in women
- Visualizing structures at the T4/5 vertebral level
- Visualizing structures in the superior mediastinum
- Visualizing the margins of the heart
- Where to listen for heart sounds
- How to visualize the pleural cavities and lungs
- Where to listen to right lung sounds
- Where to listen to left lung sounds

Pelvis and perineum

- Identification of structures in the urogenital triangle of women
- Identification of structures in the urogenital triangle of men

Abdomen

- How to find the superficial inguinal ring
- How to determine lumbar vertebral levels
- Visualizing structures at the L1 vertebral level
- Visualizing the position of major blood vessels
- Using abdominal quadrants to locate major viscera
- Defining surface regions to which pain from the gut is referred
- Where to find the kidneys and spleen

Lower limb

- Avoiding the sciatic nerve
- Finding the femoral artery in the femoral triangle
- Identifying structures around the knee
- Visualizing the contents of the popliteal fossa
- Finding the tarsal tunnel
- Identifying tendons around the ankle and in the foot
- Finding the dorsalis pedis artery
- Identifying major superficial veins
- Where to take peripheral arterial pulses in the lower limb

Upper limb

- Visualizing the axilla, its contents and related structures
- Locating the brachial artery in the arm
- Locating the triceps brachii tendon and the position of the radial nerve
- Identifying the cubital fossa and its contents
- Identifying tendons and locating major vessels and nerves in the distal forearm
- Identifying the position of the flexor retinaculum and the recurrent branch of the median nerve
- Visualizing the positions of the superficial and deep palmar arches
- Where to take peripheral arterial pulses in the upper limb

Head and neck

- Visualizing structures at the CIII/CIV and CVI vertebral levels
- How to outline the anterior and posterior triangles of the neck
- How to locate the cricothyroid ligament (membrane)
- How to find the thyroid gland

- Where to take peripheral arterial pulses in the head and neck
- Testing eye movements – demonstration illustrating the muscle involved in each activity.

ANIMATIONS OF PRACTICAL PROCEDURES

A selection of key practical procedures created especially for *Kumar & Clark*.

- Arterial cannulation
- Arterial puncture
- Bladder catheterization: female
- Bladder catheterization: male
- Central venous catheterization (CVC): jugular vein
- Central venous catheterization (CVC): subclavian vein
- Joint aspiration
- Lumbar puncture
- Venepuncture

HEART AND LUNG SOUNDS

Ten pulmonary and 12 cardiac sounds which can be either heard on their own or accompanied by an instructive narrative. This workshop has been prepared by Dr Salvatore Mangione, and we are grateful for the opportunity to make it available to readers of *Kumar & Clark*.

■ CARDIAC AUSCULTATION:

Opening snap

Aortic regurgitation and systolic flow murmur

Pericardial friction rub

S3 gallop

Mid-systolic click

Patent ductus arteriosus

Early-systolic ejection sound

Aortic stenosis

S4 gallop

Mitral regurgitation

Aortic regurgitation

Mitral stenosis and opening snap

■ PULMONARY AUSCULTATION:

Bronchial breath sounds

Crackles

Wheezes

Vesicular breath sounds

Pleural friction rub

Bronchial breath sounds and late-inspiratory crackles

Late-inspiratory squeak

Amphoric breath sounds

Whispered pectoriloquy

Preface to the Eighth Edition

Clinical Medicine was first published in 1987 and has since become firmly established in medical schools across the world. Well over a million copies have been sold worldwide. We are delighted with its success and strive constantly to ensure the content is what is required by medical students, trainees, healthcare professionals and practising doctors. Our readers worldwide provide us with a great deal of feedback and advice on a regular basis and this is incorporated into the book. We are very grateful for your input.

The previous two editions of *Kumar & Clark's Clinical Medicine* won first prize in the BMA Book Awards Medicine Category. The judges described the seventh edition as 'the primary, must-have textbook for any budding doctor, and is the "gold-standard" thorough guide to clinical medicine its forefathers were'. The eighth edition continues to strive for excellence. We hope that we have managed to provide what is frequently highly complex information in an accessible and concise fashion.

As well as focusing on the foundations of medicine, we aim to keep abreast of the many rapid developments in our chosen profession. Medicine continues to develop and improve at an astonishing rate. New technologies have impacted on diagnostic processes, and targeted therapies have been designed for many conditions. Knowledge gained from Genome-Wide Association Studies (GWAS) has been a major influence in identifying the genetic markers of several diseases. Yet some diseases continue to pose a challenge; causation may not be a single gene but multifactorial to include environmental factors. All these aspects of genetic medicine are fully discussed throughout the book.

There is no doubt that, with fast air travel across the world, infectious diseases are now truly global. Distribution, incidence and prevalence of these diseases may vary from country to country but the threat of pandemics is ever present. Infection control is not only a local issue but a worldwide challenge that involves us all. Non-communicable diseases are also on the increase. These include obesity and diabetes, which are increasing at an alarming rate, not only in the Western world but also in developing countries as they become more affluent.

To allow for fuller discussion of diseases posing particular problems to specific parts of the world, our online resource contains chapters written by members of our International Advisory Board covering topics impacting significantly both on their practice and on students and doctors choosing to travel to experience medicine in different parts of the world.

In many parts of the world the doctor-patient relationship is becoming more of a partnership, with the patient being involved in the decision-making process. Treatments are being individualized and modified to suit patients' lifestyles, leading to increased success in concordance. These changing aspects of medical care are highlighted where appropriate throughout the book.

Finally, we would like to thank very warmly all our colleagues and readers who continue to bombard us with new ideas and suggestions. We are most grateful for this - it helps keep the book alive and right up to date!

This book will support WaterAid (www.wateraid.org).

The Kumar & Clark family of books, which now contains most medical specialties, continues to expand with the latest addition being *Kumar & Clark's Medical Management and Therapeutics*. This concise clinical management handbook is designed to help the ward- or surgery-based student, trainee or doctor.

- *Kumar & Clark's Medical Management and Therapeutics*
- Ballinger: *Essentials of Kumar & Clark's Clinical Medicine*
- Henry & Thompson: *Clinical Surgery*
- O'Reilly et al.: *Essentials of Obstetrics and Gynaecology*
- Thalange et al.: *Essentials of Paediatrics*
- Franklin et al.: *Essentials of Clinical Surgery*
- Puri: *Essentials of Psychiatry*
- Kumar & Clark: *1000 Questions and Answers from Clinical Medicine*
- Smith et al.: *Pass Finals*
- Kumar & Clark: *Acute Clinical Medicine*

Acknowledgements

A book of this size could never be completed without the help and advice of many. We would like to thank our many colleagues who have helped in the preparation of this edition by giving us useful advice, helping us to collect photographs and reading the manuscripts to make sure that the contents are totally up to date. In particular, we would like to acknowledge Professor Geoffrey Dushieko (viral hepatitis), Professor Jo Martin (pathology) and Dr Susannah Leaver for general help.

We are delighted to welcome several new contributors to this edition. We would like to thank the authors they replace who have stepped down from the book after many years of commitment and loyalty: • Professor Len Doyle (Ethics), • Dr Christopher Mallinson (Communication), • Professor Ray Iles (Molecular cell biology and human genetics), • Professor Roger Finch (Infectious diseases, tropical medicine and sexually transmitted infection), • Dr David Silk and Dr Peter Fairclough (Gastrointestinal disease), • Professor Juliet Compston (Rheumatology and bone disease), • Professor Stephen Holgate, and Professor Alisdair Geddes (Environmental medicine), and • Dr Charles Clarke (Neurological disease).

Our ward rounds and outpatient reviews are a continuing source of evidence-based education and we are very grateful to our specialist registrars and junior trainees, including Foundation officers, as well as our own medical students who continue to stimulate us by asking penetrating questions.

Our travels around the world give us much insight into the practice of medicine and we would like to thank the many colleagues who have escorted us through their hospitals and medical schools. We are grateful to those who write to us, and we are extremely grateful to our International Advisory Board. Members provide very helpful advice about their regions and write the online-only chapters. In particular we would like to thank Professor Janaka de Silva for his advice, expertise and careful editing of these online contributions.

We are extremely grateful for the skill and support of our publisher, Elsevier, whose staff have maintained a commitment and loyalty to the book. We would like to acknowledge: Pauline Graham, our commissioning editor, who has taken us through this new edition; the production team of Lucy Boon (project manager), Jennifer Rose and Stewart Larking (design and illustration), and Alison Whitehouse and Ailsa Laing (content development specialists), who have all contributed to the production of this extremely high quality edition. We are also grateful for the meticulous work of the copy editors and proof readers. We would also like to express our sincere thanks to the many other people behind the scenes who have contributed in so many ways; we thank them for their loyalty and commitment.

Finally, we would like to thank Sophie Rambaud, Jillian Linton and the Princess Grace Hospital, London, for administrative assistance.

ETHICS AND THE LAW

ETHICS: AN INTRODUCTION

The practice of medicine is inherently moral:

- Biomedical expertise and clinical science has to be applied by and to people.
- Medical decisions are underpinned by values and principles.
- Potential courses of action will have implications that are often uncertain.
- Technological advancements sometimes have unintended or unforeseen consequences.

The profession has to agree on its collective purpose, aims and standards. People are much more than a collection of symptoms and signs – they have preferences, priorities, fears and hopes. Doctors too are much more than interpreters of symptoms and signs – they also have preferences, priorities, fears and hopes. Ethics is part of practice; it is a practical pursuit.

The study of the moral dimension of medicine is known as **medical ethics** in the UK, and **bioethics** internationally. To become and to practise as a doctor requires an awareness of, and reflection on, one's ethical attitudes. All of us have personal values and moral intuitions. In the field of ethics, a necessary part of learning is to become aware of the assumptions on which these personal values are based, to reflect on them critically, and to listen and respond to challenging or opposing beliefs.

Ethics is commonly characterized as the consideration of big moral questions that preoccupy the media: questions about cloning, stem cells and euthanasia are what many

immediately think of when the words 'medical ethics' are used. However, ethics pervades all of medicine. The daily and routine workload is also rife with ethical questions and dilemmas: introductions to patients, dignity on the wards, the use of resources in clinic, the choice of antibiotic and the medical report for a third party, are as central to ethics as the issues that absorb the popular representation of the subject.

The study and practice of ethics incorporate knowledge, cognitive skills such as reasoning, critique and logical analysis, and clinical skills. Abstract ethical understanding has to be integrated with other clinical knowledge and applied thoughtfully and appropriately in practice.

ETHICAL PRACTICE: SOURCES, RESOURCES AND APPROACHES

To engage with an ethical issue in clinical practice depends on:

- discerning the relevant moral question(s)
- looking at the relevant ethical theories and/or tools
- identifying applicable guidance (e.g. from a professional body)
- integrating the ethical analysis with an accurate account of the law (both national and international).

Personal views must be taken into account, but other perspectives should be acknowledged and supported by reasoning, and located in an accurate understanding of the current law and relevant professional guidance.

ETHICAL THEORIES AND FRAMEWORKS

Key ethical theories are summarized in [Box 1.1](#).

Box 1.1 Key ethical theories

Deontology: a universally applicable rule or duty-based approach to morality, e.g. a deontologist would argue that one should always tell truth irrespective of the consequences.

Consequentialism: an approach that argues that morality is located in consequences. Such an approach will focus on likely risks and benefits.

Virtue ethics: offers an approach in which particular traits or behaviours are identified as desirable.

Rights theory: assesses morality with reference to the justified claims of others. Rights are either 'natural' and arise from being human, or legal, and therefore enforceable in court. Positive rights impose a duty on another to act whilst negative rights prohibit interference by others.

Narrative ethics: an approach that argues morality is embedded in the stories shared between patient and clinician and allows for multiple perspectives.

General Medical Council. The 21st Century Doctor: Understanding the Doctors of Tomorrow. London: GMC; 2010.

Many doctors find that ethical frameworks and tools which focus on the application of ethical theory to clinical problems are useful. Perhaps the best known is the 'Four Principles' approach, in which the principles are:

1. **Autonomy:** to allow 'self-rule', i.e. let patients make their own choices and to decide what happens to them
2. **Beneficence:** to do good, i.e. act in a patient's best interests
3. **Non-maleficence:** avoid harm
4. **Justice:** treat people equitably and fairly.

For some, a consistent process that incorporates the best of each theoretical approach is helpful. So, whatever the ethical question, one should:

- summarize the problem and state the moral dilemma(s)
- identify the assumptions being made or to be made
- analyse with reference to ethical principles, consequences, professional guidance and the law
- acknowledge other approaches and state the preferred approach with explanation.

People respond differently to ethical theories and approaches. Do not be afraid to experiment with ways of thinking about ethics. It is worthwhile understanding other ethical approaches, even in broad terms, as it helps in understanding how others might approach the same ethical problem, especially given the increasingly global context in which healthcare is delivered.

PROFESSIONAL GUIDANCE AND CODES OF PRACTICE

As well as ethical theories and frameworks, there are codes of practice and professional guidelines. For example, in the UK, the standards set out by the General Medical Council (GMC) are the basis on which doctors are regulated within the UK: if a doctor falls below the expectations of the GMC, disciplinary procedures may follow, irrespective of the harm caused or whether legal action ensues. In other countries, similar professional bodies exist to license doctors and

regulate healthcare. All clinicians should be aware of the regulatory framework and professional standards in the country within which they are practising.

Increasingly, ethical practice and professionalism are considered significant from the earliest days of medical study and training. In the UK, attention has turned to the standards expected of medical students. For example, in the UK, all medical schools are required to have 'Fitness to Practise' procedures. Students should be aware of their professional obligations from the earliest days of their admission to a medical degree. All medical schools are effectively vouching for a student's suitability for provisional registration at graduation. Medical students commonly work with patients from the earliest days of their training and are privileged in the access they have to vulnerable people, confidential information and sensitive situations. As such, medical schools have particular responsibilities to ensure that students behave professionally and are fit to study, and eventually to practise, medicine.

The Hippocratic Oath, although well-known, is outdated and something of an ethical curiosity, with the result that it is rarely, if ever, sworn. The symbolic value of taking an oath remains, however, and many medical schools expect students to make a formal commitment to maintain ethical standards.

THE LAW

As it pertains to medicine, the law establishes boundaries for what is deemed to be acceptable professional practice. The law that applies to medicine is both national and international, e.g. the European Convention on Human Rights ([Box 1.2](#)). Within the UK, along with other jurisdictions, both statutes and common law apply to the practice of medicine ([Box 1.3](#)).

The majority of cases involving healthcare arise in the civil system. Occasionally, a medical case is subject to criminal law, e.g. when a patient dies in circumstances that could constitute manslaughter.

Box 1.2 European Convention on Human Rights

Substantive rights which apply to evaluating good medical practice

- Right to life (Article 2)
- Prohibition of torture, inhuman or degrading treatment or punishment (Article 3)
- Prohibition of slavery and forced labour (Article 4)
- Right to liberty and security (Article 5)
- Right to a fair trial (Article 6)
- No punishment without law (Article 7)
- Right to respect for private and family life (Article 8)
- Freedom of thought, conscience and religion (Article 9)
- Freedom of expression (Article 10)
- Right to marry (Article 12)
- Prohibition of discrimination (Article 14)

RESPECT FOR AUTONOMY: CAPACITY AND CONSENT

Capacity

Capacity is at the heart of ethical decision-making because it is the gateway to self-determination ([Box 1.4](#)). People are able to make choices only if they have capacity. The assessment of capacity is a significant undertaking: a patient's

Box 1.3 Statutes and common law

Statutes

- Primary legislation made by the state, e.g. Acts of Parliament in the UK, such as the Mental Capacity Act 2005
- Secondary (or delegated) legislation: supplementary law made by an authority given the power to do so by the primary legislation
- Implementation (or statutory) guidance, e.g. the Mental Health Act Code of Practice

Common law

- Judicial decisions made in cases: these establish precedents that are then applied to future cases
- Whether a decision constitutes a precedent depends on which court made the decision – higher level courts have authority over lower level courts

freedom to choose depends on it. If a person lacks capacity, it is meaningless to seek consent. In the UK, the Mental Capacity Act 2005 sets out the criteria for assessing whether a person has the capacity to make a decision (see Ch. 23, p. 1191).

Assessment of capacity is not a one-off judgement. Capacity can fluctuate and assessments of capacity should be regularly reviewed. Capacity should be understood as task-oriented. People may have capacity to make some choices but not others and capacity is not automatically precluded by specific diagnoses or impairments. The way in which a doctor communicates can enhance or diminish a patient's capacity, as can pain, fatigue and the environment.

Box 1.4 Principles of self-determination^a

- Every adult has the right to make his/her own decisions and to be assumed to have capacity unless proved otherwise.
- Everyone should be encouraged and enabled to make his/her own decisions, or to participate as fully as possible in decision-making.
- Individuals have the right to make eccentric or unwise decisions.
- Proxy decisions should consider best interests, prioritizing what the patient would have wanted, and should be the 'least restrictive of basic rights and freedoms'.

^aPrinciples underlying the Mental Capacity Act 2005 (England and Wales), which applies to patients over the age of 16 years.

Consent

Consent is integral to ethical and lawful practice. To act without, or in opposition to, a patient's expressed, valid consent is, in many jurisdictions, to commit an assault or battery. Obtaining informed consent fosters choice and gives meaning to autonomy. Valid consent is:

- given by a patient who has capacity to make a choice about his or her care
- voluntary, i.e. free from undue pressure, coercion or persuasion
- sufficiently informed
- continuing, i.e. patients should know that they can change their mind at any time.

The basis of informed consent

Those seeking consent for a particular procedure must be competent in the knowledge of how the procedure is performed and its problems. Whilst it is common and good practice for written information to be provided to patients, the existence of written material and a consent form does not remove the responsibility to talk to the patient. The information given to a patient should be that which a 'reasonable person' would require whilst being alert to the particular priorities and concerns of individuals. Information shared should:

- cover risks and benefits
- explain possible consequences of treatment and non-treatment
- explain options
- disclose uncertainty; this should be as much part of the discussion as sharing what is well-understood.

Patients should be encouraged to ask questions and express their concerns and preferences. Since it is the health and lives of patients that are potentially at risk, the moral focus of such disclosure should be on what is acceptable to patients rather than to the professionals.

Consent in educational settings

Much medical education and training takes place in the clinical environment. Future doctors have to learn new skills and apply their knowledge to real patients. However, patients must be given a choice as to whether they wish to participate in educational activities. The principles of seeking consent for education are identical to those applied to clinical situations.

Advance decisions

Advance decisions (sometimes colloquially described as 'living wills') enable people to express their wishes about future treatment or interventions. The decisions are made in anticipation of a time when a person ceases to have capacity. Different countries have differing approaches to advance decision-making and it is necessary to be aware of the relevant law in the area in which one is practising. Within the UK, advance decisions are governed by legislation, for example the Mental Capacity Act 2005 applies in England and Wales. The criteria for a legally valid advanced decision are that it is:

- made by someone with capacity
- made voluntarily
- based on appropriate information
- specific and applicable to the situation in which it is being considered.

In practice, it is often the requirement of specificity that is most difficult for patients to fulfil because of the inevitable uncertainty surrounding future illness and potential treatments or interventions. There is one difficulty that for many goes to the heart of an ethical objection to advance decision-making, namely that it is difficult to anticipate the future and how one is likely to feel about that future.

Scope

An advance decision can be made to refuse treatment and to express preferences, but cannot be used to demand treatment. In general, no patient has the right to demand or request treatment that is not clinically indicated. Therefore it would be inconsistent to allow patients to include in their advance decisions requests for specific treatments,

procedures or interventions. An advance decision cannot be used to refuse basic care such as maintaining hygiene.

Format

Advance decisions are made orally or in writing. However, advance decisions on the withdrawal or withholding of life-sustaining treatment must be in written form and witnessed and the decision should state explicitly that it is intended to apply even to life-saving situations. The more informal and nonspecific the advance decision is, the more likely it is to be challenged or disregarded as being invalid. If working in a country where advance decisions are recognized, clinicians should make reasonable attempts to establish whether there is a valid advance decision in place and the presumption is to save life where there is ambiguity about either the existence or content of an advance decision. Advance decisions should be periodically reviewed and amendments, revocations or additions are possible provided that the person concerned still has capacity.

Ethical and practical rationale

The ethical rationale for the acceptance of advance decisions is usually said to be respect for patient autonomy and represents the extension of the right to make choices about healthcare in the future. True respect for autonomy and the freedom to choose necessarily involves allowing people to make choices that others might consider misguided. Some suggest that giving patients the opportunity to express their concerns, preferences and reservations about the future management of their health fosters trust and effective relationships with clinicians. However, it could also be argued that none of us will ever have the capacity to make decisions about our future care because the person we become when ill is qualitatively different from the person we are when we are healthy.

Lasting power of attorney

Many countries allow for the appointment of a proxy, or for a third party, to make substituted judgements for people lacking capacity. In England and Wales, consent or refusal can be expressed by someone who has been granted a lasting power of attorney (LPA). Once a person's lack of capacity has been registered with the Public Guardian and the lasting power of attorney granted, the person holding the power of attorney is charged with representing a patient's best interests. Therefore, it is imperative to establish whether there is a valid LPA in respect of an incapacitated patient and to adhere to the wishes of the person acting as attorney. The only circumstances in which clinicians need not follow the LPA is where the attorney appears not to be acting in the patient's best interests. In such situations, the case should be referred to the Court of Protection. Like advance decisions, the ethical rationale for the existence of LPAs is that prospective autonomy is desirable and facilitates informed care, rather than second-guessing patient preferences.

Best interests of patients who lack capacity

Where an adult lacks capacity to give consent, and there is no valid advance decision or power of attorney in place, clinicians are obliged to act in the patient's best interests. This encompasses more than an individual's best *medical* interests. In practice, the determination of best interests is likely to involve a number of people, for example members of the

healthcare team, professionals with whom the patient has a longer-term relationship, and relatives and carers.

In England and Wales, an Independent Mental Capacity Advocacy Service provides advocates for patients who lack capacity and have no family or friends to represent their interests. 'Third parties' in such a situation, including Independent Mental Capacity Advocates, are not making decisions; rather, they are being asked to give an informed sense of the patient and his or her likely preferences. In some jurisdictions, e.g. in North America, clinical ethicists play an advocacy role and seek to represent the patient's best interests.

Provision or cessation of life-sustaining treatment

A common situation requiring determination of a patient's best interests is the provision of life-sustaining treatment, often at the end of life, for a patient who lacks capacity and has neither advance decision nor an attorney. It is considered acceptable not to use medical means to prolong the lives of patients where:

- Based on good evidence, the team believes that further treatment will not save life
- The patient is already imminently and irreversibly close to death
- The patient is so permanently or irreversibly brain damaged that he or she will always be incapable of any future self-directed activity or intentional social interaction.

Moral and religious beliefs vary widely and, in general, decisions not to provide or continue life-sustaining treatment should always be made with as much consensus as possible amongst both the clinical team and those close to the patient. Where there is unresolvable conflict between those involved in decision-making, a court should be consulted. In emergencies in the UK, judges are always available in the relevant court.

Where clinicians decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients, the legal rationale is that they are acting in the patient's best interests and seeking to minimize suffering rather than intending to kill, which would constitute murder. In ethical terms, the significance of intention, along with the moral status of acts and omissions, is integral to debates about assisted dying and euthanasia.

Assisted dying

Currently in many countries, there is no provision for lawful assisted dying. For example, physician-assisted suicide, active euthanasia and suicide pacts are all illegal in the UK. In contrast, some jurisdictions, including the Netherlands, Switzerland, Belgium and certain states in the USA, permit assisted dying. However, even where assisted dying is not lawful, withholding and withdrawing treatment is usually acceptable in strictly defined circumstances, where the intention of the clinician is to minimize suffering, not to cause death. Similarly, the doctrine of double effect may apply. It enables clinicians to prescribe medication that has as its principal aim, the reduction of suffering by providing analgesic relief but which is acknowledged to have side-effects such as the depression of respiratory effort (e.g. opiates). Such prescribing is justifiable on the basis that the intention is benign and the side-effects, whilst foreseen, are not intended to be the primary aim of treatment. End-of-life care pathways, which provide for such approaches where necessary, are discussed in [Chapter 10](#).

FURTHER READING

Heath I. Opt in not out: why is patient's consent presumed for cardiopulmonary resuscitation? *BMJ* 2011; 343:5251.

Although assisted dying is unlawful in the UK, the Director of Public Prosecutions (DPP) has issued guidance on how prosecution decisions are made in response to a request from the courts, following an action brought by Debbie Purdy. Thus, there are now guidelines that indicate what circumstances are likely to weigh either in favour of, or against, a prosecution. Nevertheless, the law itself is unchanged by the DPP's guidance: for a clinician to act to end a patient's life remains a criminal offence.

Mental health and consent

The vast majority of people being treated for psychiatric illness have capacity to make choices about healthcare. However, there are some circumstances in which mental illness compromises an individual's capacity to make his or her own decisions. In such circumstances, many countries have specific legislation that enables people to be treated without consent on the basis that they are at risk to themselves and/or to others.

People who have, or are suspected of having, a mental disorder may be detained for assessment and treatment in England and Wales under the Mental Health Act 2007 (which amended the 1983 statute). There is one definition of a mental disorder for the purposes of the law: The Mental Health Act 2007 defines a mental disorder as 'any disorder or disability of the mind'. Addiction to drugs and alcohol is excluded from the definition. Appropriate medical treatment should be available to those who are admitted under the Mental Health Act. In addition to assessment and treatment in hospital, the legislation provides for Supervised Community Treatment Orders, which consist of supervised community treatment after a period of detention in hospital. The law is tightly defined with multiple checks and limitations which are essential given the ethical implications of detaining and treating someone against his or her will.

Even in situations in which it is lawful to give a detained patient psychiatric treatment compulsorily, efforts should be made to obtain consent if possible. For concurrent physical illness, capacity should be assessed in the usual way. If the patient does have capacity, consent should be obtained for treatment of the physical illness. If a patient lacks capacity because of the severity of a psychiatric illness, treatment for physical illness should be given on the basis of best interests or with reference to a proxy or advance decision, if applicable. If treatment can be postponed without seriously compromising the patient's interests, consent should be sought when the patient once more has capacity.

Consent and children

Where a child does not have the capacity to make decisions about his or her own medical care, treatment will usually depend upon obtaining proxy consent. In the UK, consent is sought on behalf of the child from someone with 'parental responsibility'. In the absence of someone with parental responsibility, e.g. in emergencies where treatment is required urgently, clinicians proceed on the basis of the child's best interests.

Sometimes parents and doctors disagree about the care of a child who is too young to make his or her own decisions. Here, both national and European case law demonstrates that the courts are prepared to override parental beliefs if they are perceived to compromise the child's best interests. However, the courts have also emphasized that a child's best *medical* interests are not necessarily the same as a child's best *overall* interests. Whenever the presenting patient is a child, clinicians are dealing with a family unit. Sharing

decisions, and paying attention to the needs of the child as a member of a family, are the most effective and ethical ways of practising.

As children grow up, the question of whether a child has capacity to make his or her own decisions is based on principles derived from a case called *Gillick v. West Norfolk and Wisbech Area Health Authority*, which determined that a child can make a choice about his or her health where:

- The patient, although under 16, can understand medical information sufficiently
- The doctor cannot persuade the patient to inform, or give permission for the doctor to inform, his or her parents
- In cases where a minor is seeking contraception, the patient is very likely to have sexual intercourse with or without adequate contraception
- The patient's mental or physical health (or both) are likely to suffer if treatment is not provided
- It is in the patient's best interests for the doctor to treat without parental consent.

The *Gillick* case recognized that children differ in their abilities to make decisions and established that function, not age, is the prime consideration when considering whether a child can give consent. Situations should be approached on a case-by-case basis, taking into account the individual child's level of understanding of a particular treatment. It is possible (and perhaps likely) that a child may be considered to have capacity to consent to one treatment but not another. Even where a child does not have capacity to make his or her own decision, clinicians should respect the child's dignity by discussing the proposed treatment even if the consent of parents also has to be obtained.

In the UK, once a child reaches the age of 16, the Mental Capacity Act 2005 states that he or she should be treated as an adult save for the purposes of advance decision-making and appointing a lasting power of attorney.

CONFIDENTIALITY

Confidentiality is essential to therapeutic relationships. If clinicians violate the privacy of their patients, they risk causing harm, disrespect autonomy, undermine trust, and call the medical profession into disrepute. The diminution of trust is a significant ethical challenge, with potentially serious consequences for both the patient and the clinical team. Within the UK, confidentiality is protected by common and statutory law. Some jurisdictions make legal provision for privacy. Doctors who breach the confidentiality of patients may face severe professional and legal sanctions. For example, in some jurisdictions, to breach a patient's confidentiality is a statutory offence.

Respecting confidentiality in practice

Patients should understand that information about them will be shared with other clinicians and healthcare workers involved in their treatment. Usually, by giving consent for investigations or treatment, patients are deemed to give their implied consent for information to be shared within the clinical team. Very rarely, patients might object to information being shared even within a team. In such situations, the advice is that the patient's wish should be respected unless it compromises treatment. In almost all clinical circumstances, therefore, the confidentiality of patients must be

Confidentiality

respected. Unfortunately, confidentiality can be easily breached inadvertently. For example, clinical conversations take place in lifts, corridors and cafes. Even on wards, confidentiality is routinely compromised by the proximity of beds and the visibility of whiteboards containing medical information. Students and doctors should be alert to the incidental opportunities for breaches of confidentiality and seek to minimize their role in unwittingly revealing sensitive information.

When confidentiality must or may be breached

The duty of confidence is not absolute. Sometimes, the law requires that clinicians must reveal private information about patients to others, even if they wish it were otherwise (Box 1.5). There are also circumstances in which a doctor has the discretion to share confidential information within defined terms. Such circumstances highlight the ethical tension between the rights of individuals and the public interest.

Aside from legal obligations, there are three broad categories of qualifications that exist in respect of the duty of confidentiality, namely:

1. The patient has given consent.
2. It is in the patient's best interests to share the information but it is impracticable or unreasonable to seek consent.
3. It is in the public interest.

These three categories are useful as a framework within which to think about the extent of the duty of confidentiality and they also require considerable ethical discretion in practice, particularly in relation to situations where sharing confidential information might be considered to be in the 'public interest'. In England and Wales, there is legal guidance on what constitutes sufficient 'public interest' to justify sharing confidential information, which is derived from the case of *W v. Egdel*. In that case, the Court of Appeal held that only the 'most compelling circumstances' could justify a doctor acting contrary to the patient's perceived interest in the absence of consent. The court stated that it would be in the public interest to share confidential information where:

- there is a real and serious risk of harm
- the risk is of physical harm
- there is a risk to an identifiable individual or individuals.

Consent should be sought wherever possible, and disclosure on the basis of the 'public interest' should be a last resort. Each case must be weighed on its own individual merits and a clinician who chooses to disclose confidential information on the ground of 'public interest' must be prepared to justify his or her decision. Even where disclosure is justified, confidential information must be shared only with those who need to know.

If there is perceived public interest risk, does a doctor have a duty to warn? In some jurisdictions, there is a duty to warn

but in England and Wales, there is no professional duty to warn others of potential risk. The judgement of *W v. Egdel* provides a justification for breaches of confidence in the public interest but it does not impose an obligation on clinicians to warn third parties about potential risks posed by their patients.

RESOURCE ALLOCATION

Resources should be considered broadly to encompass all aspects of clinical care, i.e. they include time, knowledge, skills and space, as well as treatment. In circumstances of scarcity, waste and inefficiency of any resource are of ethical concern.

Access to healthcare is considered to be a fundamental right and is captured in international law since it was included in the Universal Declaration of Human Rights. However, resources are scarce and the question of how to allocate limited resources is a perennial ethical question. Within the UK, the courts have made it clear that they will not force NHS Trusts to provide treatments which are beyond their means. Nevertheless, the courts also demand that decisions about resources must be made on reasonable grounds.

Fairness

Both ethically and legally, prejudice or favouritism is unacceptable. Methods for allocating resources should be fair and just. In practice, this means that scarce resources should be allocated to patients on the basis of their comparative need and the time at which they sought treatment. It is respect by clinicians for these principles of equality – equal need and equal chance – that fosters fairness and justice in the delivery of healthcare. For example, a well-run Accident and Emergency Department will draw on the principles of equality of need and chance to:

- decide who to treat first and how
- offer treatment that has been shown to deliver optimal results for minimal expense
- use triage to determine which patients are most in need and ensure that they are seen first; the queue (or waiting list) being based on need and time of presentation.

People should not be denied potentially beneficial treatments on the basis of their lifestyles. Such decisions are almost always prejudicial. For example, why single out smokers or the obese for blame, as opposed to those who engage in dangerous sports? Patients are not equal in their abilities to lead healthy lives and to make wise healthcare choices.

Education, information, economic worth, confidence and support are all variables that contribute to, and socially determine health and wellbeing. As such, to regard all people as equal competitors and to reward those who in many ways are already better off, is unjust and unfair.

Global perspectives

Increasingly, resource allocation is being considered from an international or global perspective. Beyond the boundaries of the NHS and the borders of the UK, the moral questions about the availability of, and access to, effective healthcare are rightly attracting the attention of ethicists and clinicians. Anyone who is training for, or working in, medicine in the 21st century should consider fundamental moral questions about resource allocation, in particular those being raised by issues such as:

Box 1.5 Examples of circumstances in which a doctor is required to share confidential information

- Notifiable diseases which, by virtue of public health legislation, must be notified to the relevant consultant in communicable disease control
- Court orders
- Road traffic accidents which lead to requests from the police
- Actual or suspected terrorist activity

- The role and work of pharmaceutical companies
- The mobility of trained clinicians
- The preoccupation of funded and commercial biomedical research with diseases that are prevalent in developed countries
- Notions of rights to health and life
- The status of those seeking asylum
- Persistent inequalities in health.

PROFESSIONAL COMPETENCE AND MISTAKES

Doctors have a duty to work to an acceptable professional standard. There are essentially three sources that inform what it means to be a 'competent' doctor, namely:

1. The law
2. Professional guidance from bodies such as the GMC
3. Policy.

In practice, there is frequently overlap and interaction between the categories, e.g. a doctor may be both a defendant in a negligence action and the subject of fitness to practise procedures. Professional bodies are established by, and work within, a legal framework and in order to implement policy, legislation is required and interpretative case law will often follow.

Standards and the law

In most countries, the law provides the statutory framework within which the medical profession is regulated. For example, in the UK, it is the function of the GMC to maintain the register of medical practitioners, provide ethical guidance, guide and quality assure medical education and training, and conduct fitness to practise procedures. Therefore it is the GMC that defines standards of professional practice and has responsibility for investigation when a doctor's standard of practice is questioned.

Clinicians have a responsibility not only to reflect on their own practice, but also to be aware of and, if necessary, respond to the practice of colleagues even in the absence of formal 'line management' responsibilities. In England and Wales, for example, the Public Interest Disclosure Act 1998 provides statutory protection for those who express formal concern about a colleague's performance, provided the expression of concern:

- constitutes a 'qualifying disclosure',
- is expressed using appropriate procedures, and
- is made in good faith.

Clinical negligence

Negligence is a civil claim where damage or loss has arisen as a result of an alleged breach of professional duty such that the standard of care was not, on the balance of probabilities, that which could be reasonably expected.

Of the components of negligence, duty is the simplest to establish: all doctors have a duty of care to their patients (although the extent of that duty in emergencies and social situations is uncertain and contested in relation to civil law). Whether a doctor has discharged his or her professional duty adequately is determined by expert opinion about the standards that might reasonably be expected and his or her conduct in relation to those standards. If a doctor has acted in a way that is consistent with a reasonable body of his peers and his actions or omissions withstand logical analysis, he

or she is likely to meet the expected standards of care. Lack of experience is not taken into account in legal determinations of negligence.

The commonest reason for a negligence action to fail is causation, which is notoriously difficult to prove in clinical negligence claims. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment, making it difficult to establish the actual cause.

Clinical negligence remains relatively rare and undue fear of litigation can lead to defensive and poor practice. All doctors make errors and these do not necessarily constitute negligence or indicate incompetence. Inherent in the definition of incompetence is time, i.e. on-going review of a doctor's practice to see whether there are patterns of error or repeated failure to learn from error. Regulatory bodies and medical defence organizations recommend that doctors should be honest and apologetic about their mistakes, remembering that to do so is not necessarily an admission of negligence (see p. 14). Such honesty and humility, aside from its inherent moral value, has been shown to reduce the prospect of patient complaints or litigation.

Professional bodies

Professional bodies have diverse but often overlapping roles in developing, defining and revising standards for doctors. The principal publications in which the GMC sets out standards and obligations relating to competence and performance, are 'Duties of a Doctor' and 'Good Medical Practice'.

Policy

There have been an exponential number of policy reforms that have shaped the ways in which the medical competence and accountability agendas have evolved. One of the most notable is the increase in the number of organizations concerned broadly with 'quality' and performance. The increased scrutiny of doctors' competence has found further policy translation in the development of appraisal schemes and the revalidation process. There have been other policy initiatives that adopt the rhetoric of 'quality' such as increased use of clinical and administrative targets, private finance initiatives and the development of specialist screening facilities and treatment centres.

The issue of professional accountability in medicine is a hot topic. The law, professional guidance and policy documentation provide a starting point for clinicians. Complaints and possible litigation are often brought by patients who feel aggrieved for reasons that may be unconnected with the clinical care that they have received. When patients are asked about their decisions to complain or to sue doctors, it is common for poor communication, insensitivity, administrative errors and lack of responsiveness to be cited as motivation (see p. 7). There is less to fear than doctors sometimes believe. The courts and professional bodies are neither concerned with best practice, nor with unfeasibly high standards of care. What is expected is that doctors behave in a way that accords with the practice of a reasonable doctor – and the reasonable doctor is not perfect. As long as clinicians adhere to some basic principles, it is possible to practise *defensible* rather than *defensive* medicine. It should be reassuring that complaints and litigation are avoidable, simply by developing and maintaining good standards of communication, organization and administration – and good habits begin in medical school. In particular, effective communication is a potent weapon in preventing complaints and, ultimately, encounters with the legal and regulatory systems.

COMMUNICATION

COMMUNICATION IN HEALTHCARE

Communication in healthcare is fundamental to achieving optimal patient care, safety and health outcomes. The aim of every healthcare professional is to provide care that is evidence-based and unconditionally patient-centred. Patient-centred care depends on a consulting style that fosters trust and communication skills, with the attributes of flexibility, openness, partnership, and collaboration with the patient.

Doctors work in multiprofessional teams. As modern healthcare has progressed, it is now more effective, more complex and more hazardous. Successful communication within healthcare teams is therefore vital.

What is patient-centred communication?

Patient-centred communication involves reaching a common ground about the illness, its treatment, and the roles that the clinician and the patient will assume (Fig. 1.1). It means discovering and connecting both the biomedical facts of the patient's illness in detail and the patient's ideas, concerns, expectations and feelings. This information is essential for diagnosis and appropriate management and also to gain the patient's confidence, trust and involvement.

The traditional approach of 'doctor knows best' with patients' views not being considered is very outdated. This change is spreading worldwide and is not just societal but driven by evidence about improved health outcome. There are three main reasons for this:

- Patients increasingly expect information about their condition and treatment options and want their views taken into account in deciding treatment. This does not mean clinicians totally abdicate power. Patients want their doctors' opinions and expertise and may still prefer to leave matters to the clinician.
- Many health problems are long-term conditions and patients may become experts actively involved in self-care. They have to manage their conditions and reduce risks from lifestyle habits in a partnership approach to care.

- A distinguishing feature of the healthcare professions is that patients expect humanity and empathy from their doctors as well as competence. Clinicians can usually offer practical help with patients' concerns and expectations but, if not, they can always listen supportively.

Patient-centred communication requires a good balance between:

- Clinicians asking all the questions needed to include or exclude diagnoses
- Patients being asked to express their ideas, concerns, expectations and feelings
- Clinicians explaining and advising in ways patients can understand so that they can be involved in decisions about their care.

What are the effects of communication?

Enormous benefits accrue from good communication (Box 1.6). Patients' problems are identified more accurately and efficiently, expectations for care are agreed and patients and clinicians experience greater satisfaction. Poor communication results in missed problems (Box 1.7) and concerns, strained relationships, complaints and litigation.

Box 1.6 Benefits of good communication

- Improved diagnostic accuracy
- Improved physical health outcomes (blood pressure, diabetes, asthma, pain)
- Emotional health and functioning
- Increased patient adherence
- Increased patient and clinician satisfaction
- Reduced litigation
- Improved time management and costs
- Patient safety

Diagnostic accuracy

Clinicians commonly interrupt patients after an average 24 seconds, whether or not a patient has finished explaining their problem. Uninterrupted patients will talk for 90 seconds

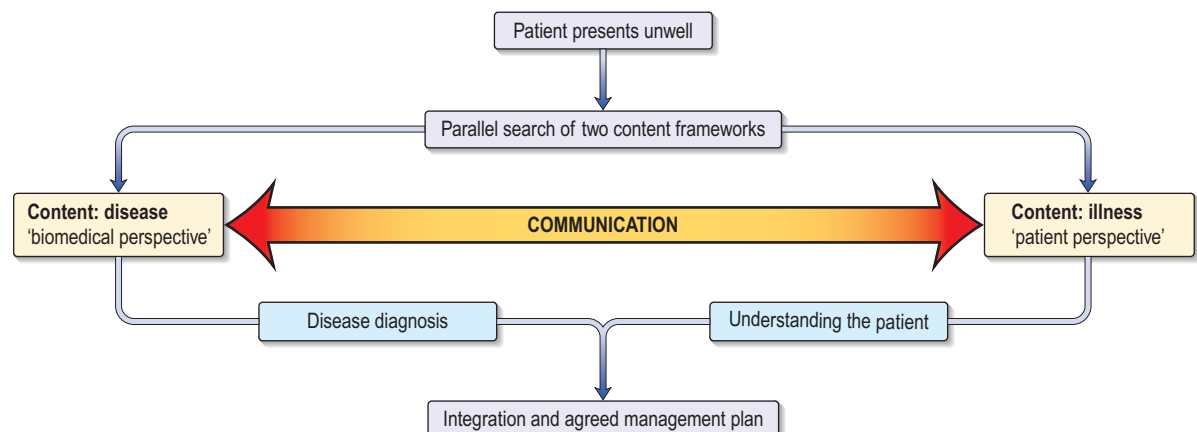

Figure 1.1 The patient-centred clinical interview. (Adapted from: Levenstein JH. In: Stewart M, Roter D, eds. *Communicating with Medical Patients*. Thousand Oaks, CA: Sage; 1989, with permission.)

**Box 1.7 Patient reports of failure to identify problems in interviews**

- 54% of complaints and 45% of concerns were not elicited
- 50% of psychological problems not elicited
- 80% of breast cancer patients' concerns remain undisclosed
- In 50% of visits, patients and doctors disagreed on the main presenting problem
- In 50% of cases, patient's history was blocked by interruption within 24 seconds

From: Simpson M, Buckman R, Stewart M et al. *The Toronto Consensus Statement*. British Medical Journal 1991; 303: 1385–1387, with permission.

on average (maximum 2.5 minutes). Clinicians are failing if a serious point is raised only as the patient is preparing to leave and this then takes longer.

Health outcomes

These are improved by good communication. Hospital visits, admissions, length of stay and mortality rate are reduced where clinicians used a biopsychosocial approach to managing people with medically unexplained symptoms. Conversely, the main predictive factor for patients developing depression on learning of the diagnosis of cancer was the way their bad news had been broken.

Adherence to treatment

Some 45% of patients are not following treatment advice properly. Errors in use of medications are costly and risk patient safety. Patients may not understand or remember what they were told, whilst others actively decide not to follow advice and commonly do not tell their doctors. Research shows that clinicians rarely check patients' understanding or views, yet such communication contributes to adherence (Practical Box 1.1).

**Practical Box 1.1****Factors which improve adherence to clinical advice****Clinician**

- Listens to and understands the patient
- Tone of voice
- Elicits all of the patient's health concerns

Patient

- Is comfortable asking questions
- Feels sufficient time is spent with the clinician

From Stewart M, Brown JB, Boon H et al. *Evidence on patient communication*. Cancer Prevention and Control 1999; 3(j):25–30, with permission.

Patient satisfaction and dissatisfaction

Satisfaction with consultations is largely a result of patients knowing they are:

- getting the best medical care
- being treated humanely as individuals and not as items on a conveyor belt.

Satisfaction with a consultation affects psychological well-being and adherence to treatment, both of which have a knock-on effect on clinical outcomes. It also reduces patient complaints and litigation (Box 1.8). Some 70% of lawsuits are a result of poor communication rather than failures of

**Box 1.8 Behaviours influencing litigation****Patients are more likely to sue if:**

- They feel deserted and devalued by the clinician
- They think information has been delivered poorly
- Authoritarian, paternalistic styles of questioning and voice have been used

Primary care physicians who have never been sued:

- Orientated patients, e.g. 'We are going to do this first and then go on to that'
- Used facilitative comments, e.g. 'uh huh, I see'
- Used active listening
- Checked understanding
- Asked patients their opinions
- Used humour and laughter appropriately
- Conducted slightly longer visits (18 versus 15 minutes)

biomedical practice. Complaints and lawsuits represent only the tip of the iceberg of discontent, as revealed by surveys of patients in hospital and primary care.

Clinician satisfaction

Healthcare professionals have a very high rate of occupational stress and burnout, which is costly both to them and to health services. Notwithstanding pressure from staffing shortages and inadequate resources, it is the quality of relationships with patients and colleagues that affects clinician satisfaction and happiness.

Time and costs

Those who integrate *patient-centred communication* into all interviews actually save time and also reduce non-essential investigations and referrals, which waste resources. Patients given the latest evidence on treatment options commonly choose more conservative management with no adverse effects on health outcomes. This has potential for considerable savings in health budgets.

Barriers and difficulties in communication

Communication is not straightforward (Box 1.9). Time constraints can prevent both doctors and patients from feeling that they have each other's attention and that they fully understand the problem from each other's perspective. Underestimation of the influence of psychosocial issues on illness and their costs to healthcare means clinicians may resort to avoidance strategies when they fear the discussion will unleash emotions too difficult to handle, upset the patient or take too much time (Box 1.10).

Patients for their part will not disclose concerns if they are anxious and embarrassed, or sense that the clinician is not interested or thinks that their complaints are trivial. Many patients have poor knowledge of how their body works and struggle to understand new information provided by doctors. Some concepts may be too unfamiliar to make sense of, even if described simply, and patients may be too embarrassed to say they don't understand. For example, when explaining fasting blood sugar levels to newly diagnosed diabetics it was found that many did not realize that there is sugar in their blood.

Clinicians are human and are often rushed and stressed. They work against the clock and in fallible systems. But as professionals, it is they, together with healthcare managers, who bear the responsibility for dealing with these difficulties and problems, not the patient.

THE MEDICAL INTERVIEW

Structure and skills for effective interviewing

Clinicians conduct some 200 000 medical interviews during their careers. Flexibility is a key skill in patient-centred communication because each patient is different. A framework helps clinicians use time productively. The example below applies to a first consultation and may vary slightly in a follow-up appointment or emergency visit.

There are seven essential steps in the medical interview:

1. Building a relationship

Because patients are frequently anxious and may feel unwell, introductions and first impressions are critical to create rapport and trust. Without rapport and trust, effective communication is impossible. Well-organized arrangements for appointments, reception and punctuality put patients at ease. Clinicians' non-verbal messages, body language and unspoken attitudes have a huge impact on the emotional tone of the interview. Seating arrangements, eye contact, facial expression and tone of voice should all convey friendliness, interest and respect.

2. Opening the discussion

The aim is to obtain all the patients' concerns, remembering that they usually have at least three (range 1–12). Ask 'What would you like to discuss today?' or 'What problems have brought you to see me today?'

Listen attentively without interrupting. Ask 'And is there something else?' to screen for any other problems before exploring the history in detail.

Only when all concerns are identified can the agenda be prioritized, balancing the patients' main concerns with the clinician's medical priorities.

3. Gathering information

The components of a complete history are shown in Table 1.1.

Table 1.1 Components of a medical interview

The nature of the key problems Clarification of these problems Date and time of onset Development over time Precipitating factors Help given to date Impact of the problem on patient's life Availability of support Patient's ideas, concerns and expectations Patient's attitude to similar problems in others Screening question

Listening skills

Attentive listening is a necessary communication skill. Ask the patient to tell the story of the problem in their own words from when it first started up to the present. Patients will recognize clinicians are listening if they look at them and not the notes or computer. Occasional nods will encourage the patient to continue. Avoid interrupting before the patient has finished talking.

Questioning styles

The way a clinician asks questions determines whether the patient speaks freely or just gives one word or brief answers (Practical Box 1.2). Start with open questions ('What problems have brought you in today?') and move to screening ('Is there anything else?'), focused ('Can you tell me more about the pain?') and closed questions ('Where is the pain?'). Open methods allow clinicians to listen and to generate their problem-solving approach. Closed questions are necessary

Practical Box 1.2

Questioning style

Closed questioning style:

Doctor: 'You say chest pain, where is the pain?' (*closed Q*)

Patient: 'Well just here' (pointing to sternum)

Doctor: 'And is it a sharp or dull pain?' (*closed Q*)

Patient: 'Quite a sharp pain'

Doctor: 'Does it go anywhere else?' (*closed Q*)

Patient: 'No, just there'

Doctor: 'And you don't smoke now do you?' (*leading Q*)

Patient: 'Well ... just the occasional one.'

Open questioning style:

Doctor: 'Tell me about the pain you've been having.' (*open/focused Q*)

Patient: 'Well it's been getting worse over the past few weeks and waking me up at night. It's just here (points to sternum), it's very sharp and I get a burning and bad acid taste in the back of my throat. I try to burp to clear it. I've taken antacids but they don't seem to be helping now and I'm a bit worried about it. I'm losing sleep and I've got a busy workload so that's a worry too.'

Doctor: 'I see. So it's bothering you quite a lot. Anything else you've noticed?' (*empathic statement, open screening Q*)

Patient: 'I've noticed I get it more after I've had a few drinks. I have been drinking and smoking a bit more recently. Actually I've been getting lots of headaches too which I've just taken Ibuprofen for.'

Doctor: 'You say you are worried, is there anything in particular that concerns you?' (*picks up on patient's cue and uses reflecting question*)

Patient: 'I wondered if I might be getting an ulcer.'

Doctor: 'I see. So this sharp pain under your breastbone with some acid reflux for several weeks is worse at night and aggravated by drinking and smoking but not relieved by antacids. You are busy at work, getting headaches, drinking and smoking a bit more and not sleeping well. You're concerned this could be an ulcer.' (*summarizing*)

Patient: 'Yes, a friend had problems like this.'

Doctor: 'I can appreciate why you might be thinking that then.' (*validation*)

Patient: 'Yes and he had to have a "scope" so I wondered whether I would need one?' (*expectation*)

Doctor: 'Well, let me explain first what I think this is and then what I would recommend next ...' (*signposting*)

to check specific symptoms but if used too early, they may narrow down and lead to inaccuracies by missing patients' problems.

Leading questions which imply the expected answer ('You've given up drinking haven't you?') risk inaccurate responses as patients may go along with the clinician rather than disagree.

4. Understanding the patient

Finding out the patient's perspective is an essential step towards achieving common ground.

Ideas, concerns and expectations (ICE)

Patients seek help because of their own ideas or concerns about their condition. If these are not heard, they may think the clinician has not got things right and then not follow advice. Moreover, any misconceptions which could affect their symptoms and ability to recover will go uncorrected. A patient's views can emerge if the clinician listens carefully and picks up on cues. But if they do not, it is necessary to ask specific questions, e.g.:

- 'What were you worried this might be?'
- 'Are there any particular concerns you have about ...?'
- 'Was there anything you were hoping we might do about this?'

Hearing patients' ideas, acknowledging their concerns and empathizing, are essential steps in engaging a patient's trust, and beginning to 'treat the whole patient'. The example in [Practical Box 1.2](#) also shows how information that may be biomedically relevant emerges while listening to patients.

Non-verbal communication

In adult conversation, some 5% of meaning derives from words, 35% from tone of voice and 60% from body language and non-verbal communication. When there is mismatch between words and tone, the non-verbal communication elements hold the truer meaning. Patients who are anxious, uneasy, puzzled or confused are more likely to communicate this through expression and/or restless activity, for example of the feet and hands, than to tell the clinician outright. The observant clinician can pick up on this: 'You seem uneasy about what I have said ...', thus inviting the patient to share their concerns.

Empathizing

Empathy has been described as 'imagination for others'. It is different from sympathy (feeling sorry for the patient), which rarely helps. Empathy is a key skill in building the patient-clinician relationship and is highly therapeutic. The starting point is attentive listening and observing patients to try and understand their predicament. This understanding then needs to be conveyed back in a supportive way. Whilst empathy is about trying to understand, the phrase 'I understand' may be met with 'how could you!' It is usually more helpful to reflect back using some of the patient's own words and ideas. For example, by saying: 'It sounds like ...' (patient heard); 'I can see you are upset' (patient seen); 'I realize that this is a shock' (acknowledgement); 'I can tell you that most people in your circumstances get angry' (accepting the patient).

Like other communication skills, empathy can be taught and learnt but it has to be genuine and cannot be counterfeited by a repertoire of routine mannerisms.

5. Sharing information

Tailoring information to what the patient wants to know and the level of detail they prefer helps them understand.

Patients generally want to know 'is this problem serious and how will it affect me; what can be done about it; and what is causing it?' Research shows patients cannot take in explanations about cause if they are still worrying about the first two concerns.

- Information must be related not only to the biomedical facts, but tailored to patients' ideas and concerns.
- Most patients want to be fully informed, irrespective of socioeconomic group.
- Most patients of all ages will understand and recall 70–80% of even the most unfamiliar, complex or alarming information if given along the guidelines shown in [Practical Box 1.3](#).

6. Reaching agreement on management

Understanding the situation is the first step but the clinician and patient also then need to agree on the best course for possible investigations and treatments.

Practical Box 1.3

Giving information

The 3E Model: Explore, Explain, Explore

Explore

Ask what the patient already knows or thinks is wrong. This allows you to confirm, correct or add new information.

Explain

Chunk and check. Give information in assimilable chunks, one thing at a time. Check after each chunk that the patient is understanding.

Signpost. 'I'll explain first of all ...'; 'Can I move on now to explain treatment options ...?'

Link. Explain the cause and effect of the condition in the context of the patient's symptoms, e.g. 'The reason you are experiencing ... is because ...'

Plain language. Clear, concise language; translate any unavoidable medical terms and write them down.

Aid recall. Simple diagrams, leaflets, recommend websites and support organizations.

Explore

'Teach back'. Use the universal precaution of always asking patients to tell you what they have understood. This is to check you have explained it clearly enough.

FURTHER READING

Royal College of Physicians. A Clinician's Guide to Record Standards 2009; <http://www.rcplondon.ac.uk/clinical-standards/hiu/medical-records>.

Negotiating the next steps – enlisting the patient's collaboration

The clinician's opinion should be given and the patient's views sought. Check if the patient wants to be involved or to leave decisions to the clinician.

Patients will adhere best when they are enlisted as partners as a result of:

- A frank exchange of information
- A negotiation of options
- Being actively involved in decisions.

Summarizing

This allows a patient to correct or add information and correct any misunderstandings. It is a feature of shared decision-making and good practice.

7. Providing closure

Summary

A final summary of the agreed course of action and next steps indicates the closing stage of the interview. Plans for follow-up and informing other healthcare professionals involved in the patient care are confirmed.

Closing

Some clinicians close the interview by asking whether the consultation has been useful, before saying goodbye.

Clinical records

All medical interviews should be well documented. Good records are the responsibility of everyone in the healthcare team (Table 1.2), as is maintenance of confidentiality. They are vital in providing best care, reducing error and ensuring patient safety.

In many countries, patients have the right to see their records, which provide essential information when a complaint or claim for negligence is made. They are also valuable as part of audit aimed at improving standards of healthcare.

Computer records are increasingly replacing written records. They include more information and overcome

Table 1.2 Essentials of record-keeping

Records should include:

Relevant clinical and psychosocial information – history and examination
Relevant findings, both positive and negative
Diagnosis including uncertainties
Investigations arranged
Test results
Correspondence, including e-mails and text messages
Decisions made
Information given to patients
Consent
Drugs or other treatments prescribed
Follow-up and referrals

Criteria for good records:^{a,b}

Clear, accurate, legible and contemporaneous
Dated and signed with printed name
Written in pen (if not electronic)
First hand
Original – never altered (using a signed, dated additional note alongside any mistake)
Kept secure

^aGMC Good Medical Practice 2012. ^bMPS Guide to Medical Records 2010; <http://www.medicalprotection.org/uk/booklets/medical-records>.

problems of legibility, for example prescription errors are reduced by 66% when electronic prescriptions replace hand-written ones. With adequate data protection, use of electronic records via the internet holds immense potential for unifying patient record systems and allowing access electronically by members of the healthcare team in primary, secondary and tertiary care sectors.

TEAM COMMUNICATION

Modern healthcare is complex and patients are looked after by multiple healthcare professionals working in shifts. Effective team communication is absolutely essential and this is never more vital than when people are busy or a patient is critically ill. Contexts for team communication include hand-over, requesting help, accepting referrals and communication in the operating theatre. Lessons from industries such as aviation and energy show how to reduce error caused by poor communication.

Problems arise when information is not transmitted, is misunderstood or is not recorded. Communication styles vary. Some people are indirect and more elaborate in their speech, whilst others go straight to the point, leaving out detail and their own rationale. Each type can feel irritated, offended or puzzled by the other and most complaints in teams relate to communication. Handover between teams is helped when everyone adopts a clear system.

Frameworks such as SBAR (Situation–Background–Assessment–Recommendation) use standardized prompt questions in four sections to ensure team members share concise and focused information at the correct level of detail (Box 1.11). This increases patient safety.

Problems also occur when people have differing opinions about treatment, which are not resolved. Hierarchies make it harder for people to speak up. This can be dangerous if, for example, a nurse or junior doctor feels unable to point out an error, offer information or ask a question. Hinting and hoping is not good communication. Team leaders who 'flatten' the hierarchy by knowing and using people's names, routinely have briefings and debriefings, do not let their own self-image override doing the right thing and positively

Box 1.11 SBAR: A structure for team communication

S – Situation	My name is ... I am the junior doctor on ward ... I am calling about Mr ..., under consultant ... The reason I am calling is ...
B – Background	The patient was admitted on ... for ... The significant medical history ... Brief summary background: medications, laboratory results, diagnostic tests, procedures
A – Assessment	Summarize relevant information gathered on examination of patient, charts and results Vital signs: heart rate, respiratory rate, oxygen saturation, BP, temperature; assess for alertness, voice, pain, unresponsiveness (AVPU) Early warning or similar score What has changed Interpretation of this
R – Recommendation (examples)	I think the patient may need ... I need your advice on how to proceed ... I think the patient needs urgent review in the next 10 min (timeframe) ...

encourage colleagues to speak up, reduce the number of adverse events. Teamwork requires collaboration, open sharing of ideas and being prepared to discuss weaknesses and errors. These skills can be learned.

Communication on discharge is just as essential and primary care physicians need sufficient information, including information about medication, to safely continue care.

COMMUNICATING IN DIFFICULT SITUATIONS

The skills outlined previously form the basis of any patient interview but some interviews are particularly difficult:

- Breaking bad news
- When things go wrong, complaints and lawsuits
- Cultural differences
- People with impaired faculties for communication.

Breaking bad news

Bad news is any information which is likely to drastically alter a patient's view of the future. The way news is broken has an immediate and long-term effect. When skilfully performed, the patient and family are enabled to understand, cope and make the best of even very bad circumstances. These interviews are difficult because biomedical measures may be of little or no help, and patients are upset and can react unpredictably. The clinician may also feel upset, more so if there is an element of medical mishap. The two most difficult things that clinicians report are how to be honest with the patient whilst not destroying hope, and how to deal with the patient's emotions.

Withholding information from patients or telling only the family is a thing of the past and becoming so even in parts of the world where traditionally disclosure did not occur.

Although truth can hurt, deceit hurts more. It erodes trust and deprives patients of information to make choices. Most people now express the wish to be told the truth and the evidence is that patients:

- usually know more than anyone realizes and may imagine things worse than they are
- appreciate clear information even about the worst news and want the opportunity to talk openly and ask questions, rather than join in a charade of deception
- differ in how much they can take in at a time.

A framework: the S-P-I-K-E-S strategy

Having a framework helps clinicians to present bad news in a factual, unhurried, balanced and empathic fashion whilst responding to each patient.

S – Setting

- See the patient as soon as the current information has been gathered.
- Ask not to be disturbed and hand bleeps to colleagues.
- If possible, the patient should have someone with them.
- Choose a quiet place with everyone seated and introduce everyone.
- Indicate your status, extent of your responsibility toward the patient and the time available.

P – Perception

Ask before telling. Find out what has happened to the patient since the last appointment and what has been explained or construed so far. This stage helps gauge the patient's perception, but should not be too drawn out.

I – Invitation

- Indicate you have the results and ask if the patient wants you to explain.
- Assess how much the patient would like to know.
- If patients do not want details, offer to answer any questions they may have later or to talk to a relative or friend.

K – Knowledge

If the patient wishes to know:

- Give a warning to help the patient prepare: 'I'm afraid it looks more serious than we hoped.'
- Then give the details.
- At this point, WAIT: allow the patient to think, and only continue when the patient gives some lead to follow. This pause may be a long one, commonly a matter of minutes, but useful to help patients take in the situation. Patients may shut down and be unable to hear anything further until their thoughts settle down.
- Give direct information, in small chunks. Avoid technical terms. Check understanding frequently: 'Is this making sense so far?' before moving on. Watch for signs the patient can take no more.
- Invite questions.
- Emphasize which things, for example pain and other symptoms, are fixable and which others are not.
- Be prepared for the question: 'How long have I got?' Avoid providing a figure to an individual, which is bound to be inaccurate. Common faults are to be overly optimistic. Some patients wish to know survival rates for their condition. Tell them as much as is appropriate.

Team communication

Communicating in difficult situations

Stress the importance of ensuring that the quality of life is made as good as possible from day to day.

- Provide some positive information and hope, tempered with realism.

E – Empathy

Responding to the patient's emotions is about the human side of medical care and also helps patients to take in and adjust to difficult information. A range of emotions are experienced in seriously and terminally ill patients (Box 1.12).

- Be prepared for the patient to have disorderly emotional responses of some kind. Acknowledge them early on as being what you expect and understand and wait for them to settle before continuing.
- Crying can be a release for some patients. Allow time if the patient needs it, rather than rushing in to stop the crying.
- Learn to judge which patients wish to be touched and which do not. You can always reach out and touch their chair.
- Keep pausing to allow patients to think and frame their questions.
- Watch for shutdown: stop the interview if necessary and arrange to resume later.

**Box 1.12 Emotional responses to serious illness**

- Despair
- Denial
- Anger
- Bargaining
- Depression
- Acceptance

S – Strategy and summary

Patients who have a clear plan for the next and future steps are likely to feel less anxious and uncertain. The clinician must ensure:

- The patient has understood what has been discussed because at times of emotion, misconceptions can take root
- Crucial information is written down to take away
- The patient knows how to contact the appropriate team member and thus has a safety net in place; when the next appointment is (preferably soon), who it is with and its purpose
- Family members are invited to meet the clinicians as the patient wishes and further sources of information are provided
- Everyone is bid goodbye, starting with the patient.

Follow-up

Bad news is a process and not a one-off. Patients may well not remember everything from the last visit and recapping is necessary. Always start by asking what they have understood so far. It is extremely distressing for patients to hear conflicting things from different clinicians. Keep colleagues informed and document accurately what was said to a patient and the patient's wishes.

The move from active treatment to palliative care is a difficult stage in bad news. Patients want to know what happens next. They want to know 'Will I be in pain?'; 'Can I stay at

home?'; and 'How long do I have?' Give clear answers with acknowledgement of any uncertainty. The priorities in patient care now are: relief of symptoms, quality of life and enabling the patient to settle family matters or unfinished business.

The clinician's role is to mediate between the patient, other medical staff and the patient's relatives whilst continuing to be an empathic and caring doctor.

When things go wrong

When things go wrong, as inevitably they do at some time, even in the best of medical care, it is distressing for all concerned. Doctors need to communicate honestly and clearly to minimize distress and act immediately to put matters right, if that is possible. The consultation that occurs after an adverse experience is crucial in influencing any decision to sue.

Being open is recognized as good practice internationally. Doctors should offer an apology and explain fully and promptly what has happened, and the likely short-term and long-term effects of any harm. Reluctance to say 'sorry' comes from a fear that it is an admission of fault, which later compromises liability, but guidelines from official bodies emphasize that this is not so. As well as being morally right, an honest approach decreases the trauma felt by patients and relatives following an adverse event and is more likely to lead to forgiveness. Examples of an open approach in the USA, Australia and Singapore have actually reduced costs of complaints.

Having a clear framework also helps to reduce clinicians' stress and develop their professional reputation for handling difficult situations properly.

Complaints

Much of the enormous increase in complaints and medical lawsuits is related to failures in communication. As with mishaps, clinicians tend not to deal effectively with dissatisfaction and complaints at the appropriate time, which is as soon as they happen. They may use avoiding strategies and become defensive. However, time spent when the complaint first arises can save minor inconveniences from becoming major traumas for all concerned.

The majority of complaints come from the exasperation of patients who:

- feel deserted and devalued by their clinician
- have not been able to get clear information
- feel that they are owed an apology
- are concerned that other patients will go through what they have.

Many complaints are resolved satisfactorily once these points are dealt with promptly and appropriately (Practical Box 1.4).

**Practical Box 1.4****Responding to complaints**

- Remember the complainant is still a patient to whom there is a duty of care
- Listen and express regret for distress
- Acknowledge when things have gone wrong – be objective, not resentful or defensive
- Apologize for actual or perceived shortcomings
- Provide easily understood information or explanations
- Offer appropriate redress
- Explain how things will improve
- Leave medical records strictly unaltered

These interactions are very difficult for clinicians and patients and this is an area recommended for training to help all healthcare professionals. Clinicians should work in a professional culture that regards complaints as a valuable source of feedback, which deserves to be noted, collected and used to bring improvements to services.

Lawsuits

Lawsuits, the extreme form of complaint, are commonly rooted in poor communication or miscommunication, aggravated by a sense of grievance. Some 17% of patients affected by medical injury in the UK want financial compensation or disciplinary action. Any clinician faced with a lawsuit must seek specialist advice.

Culture and communication

Whilst doctors strive to treat all patients equally, those from minority cultures receive poorer healthcare than others of the same socioeconomic status, even when they speak the same language. They experience fewer expressions of empathy, shorter consultations and fewer attempts to include them in shared decision-making. They also tend to say less in consultations.

Clinicians commonly express anxiety and uncertainty about how to respond to cultural diversity, how to use advocates (interpreters) and how to avoid causing offence.

Beliefs

We all take our culture for granted but it can profoundly affect notions about symptoms, causes of illness and appropriate behaviour and treatment.

It influences when to seek medical assistance, what patients and doctors expect of the consultation and how they communicate. In some cultures, for example, it is very difficult for a woman to see a male doctor. Sometimes, family members may think it is their duty to talk for the patient whilst the doctor will expect to talk directly with the patient. Sensitive topics may be difficult to address but failure to do so could jeopardize care. It helps to apologize if offence is inadvertently caused and explain why such questions are required. Clinicians vary too. Those from traditional cultures may have a more paternalistic style than some patients want.

Language

Patients sometimes bring a family member or friend to interpret. This can be problematic because they may not have sufficient vocabulary and may be censoring sensitive matters or expressing their own views rather than the patient's. Confidentiality cannot be guaranteed and patients may feel restricted in what they can say. Children should not be used to interpret, although they often still are.

When communicating through an advocate or interpreter, ask for the correct pronunciation of a patient's name and whether there are any cultural differences in body language. Arrange the seating to see both the patient and advocate but always look and speak directly to the patient. Speak in short phrases, avoid jargon and find out the patient's ideas, concerns and expectations. Watch for non-verbal communication and check the patient's understanding.

Clinicians sometimes worry that interpreters are editing, when long exchanges are followed by only a short summary back to them. It helps to ask interpreters to translate exactly what has been said, e.g.:

Patient: [Long explanation.]

Interpreter: She says she is sick.

Doctor: Could you please translate exactly what she said so that I can understand everything.

Interpreter: I have been feeling dizzy, my head hurts all the time and this morning I was sick.

Whilst examining the patient, ask the interpreter to stand outside the curtain. Always thank the interpreter at the end of the interview. If professional interpreters are not available, use telephone language lines or ask colleagues who speak the patient's language. Advocates are people from the patient's culture who can do more than translate. They can explain beliefs and concerns that are relevant in the patient's culture and they help patients to understand the workings of the healthcare system.

Non-verbal communication

Awareness of cultural taboos, for example handshaking, eye contact, personal space and subjects that would be offensive to talk about, can help in maintaining dignity and respect.

Paraverbal communication varies across cultures. We infer things from tone of voice, stress on words and phrases, silence, pace, and politeness conventions used. Some cultures are more open, direct and assertive than others. Some languages do not differentiate gender in common nouns and pronouns, so 'he' and 'she' may be used interchangeably. It is hardly surprising that misunderstandings occur and it can be much harder to create rapport. It is worth remembering that smiling is a universal expression of kindness and warmth.

Patients may be more or less traditional, so check out assumptions.

Patients who have impaired faculties for communication

All healthcare professionals need patience, ingenuity and willingness to learn to be able to communicate effectively with patients who have impaired communication faculties.

Impaired hearing

Some 55% of people over 60 are deaf or hard of hearing. Patients may be accompanied by a signer but less than 1% of hearing-impaired people sign. Many hard of hearing people lip-read and some commonsense tips are listed in **Practical Box 1.5**. Clinicians who mumble, speak fast or have strong accents have a responsibility to make particular efforts to be understood.

Conversation aids are available which involve a microphone and amplifier. Specially adapted textphones, Minicomms, allow people to type messages which the operator relays to the person on the phone. Mobile textphones are also available.

Practical Box 1.5

Communicating with people who are deaf or hard of hearing

- Ask if they need to lip-read you
- Position yourself on the better hearing side
- Smile and use eye contact
- Put your face in a good light
- Do not cover your face or mouth
- Use plain language
- Speak clearly but not too slowly
- Do not shout
- If stuck, write it down
- Check for understanding
- Never say 'forget it'!

Impaired vision

Patients who have visual impairment can miss non-verbal cues in communication. It may sound obvious, but it helps to make more conscious efforts to use the patient's name so they know they are being spoken to. Clinicians should avoid sudden touch, explain what they are about to do and say what they are doing as they go along. Large print information sheets should be available for those with limited vision; audio-tapes, Braille and Moon versions for blind people (<http://www.rnib.org.uk>).

Patients who have limited understanding or speech

Aphasia is a communication disorder. Even though hearing and thought processes are unaffected, patients find it hard to understand, or they know what they want to say but cannot find the words; they are literally 'lost for words'. This also affects their ability to write, gesture, draw or mime their thoughts.

Patients may have a strength in one area, for example understanding, with a weakness in another other area, e.g. expression, or vice versa.

It helps to find a quiet place without distractions, to make eye contact and get the person's attention. Speak slowly and clearly, use simple phrases and leave plenty of time between sentences to allow for the extra processing time it takes with aphasia. Make it obvious when changing the subject.

Closed questions requiring Yes or No answers are easier. Write down key words or headings that both the patient and clinician can refer to. This helps because the auditory memory needed to 'hold on to' the spoken word taxes the patient's language system. Use pictures and have pen and paper at hand if the patient can use them.

Much can be learnt from carers or watching speech and language therapists, see: <http://www.ukconnect.org/index.aspx>.

RECENT INFLUENCES ON COMMUNICATION**The internet**

The internet has revolutionized ready access to information, and in 2010 some 65% of the UK population surfed the net with medical queries. Research on its impact on the doctor-patient relationship is emerging. People report feeling more able to ask informed questions, with less fear of the unknown. Many doctors support internet use, especially post-diagnosis when it helps patients understand and manage their illness.

Some clinicians, however, fear longer consultations, demands which cannot be met, commercially-biased information and patients knowing more than them.

Public trust in information is essential, and directing patients to reputable internet sites can enhance communication.

Decision aids

Weighing up treatment benefits and risks where both may be substantial but not guaranteed is very hard for patients. Decision aids which are evidence-based, written in non-technical language and often including visual representations help people digest complex statistical information. They are reliable and from independent sources. Formats include web applications, DVDs, computer programs, leaflets and structured counseling. They are growing in number, with over 400 listed on the Cochrane register (see, e.g. <http://www.ohri.ca/decisionaid>).

Studies show they do not increase patients' anxiety and their use results in 21–44% reduction in choice of invasive surgical options over more conservative treatments without adverse effects on health.

Training in communication skills

This chapter has covered principles and practical advice on communication in healthcare. There is clear evidence that communication ability is not just innate; it is a professional skill that can be improved and used in everyday practice. The need for clinicians to continually update their skills is recognized as working patterns in healthcare, societal expectations and technological advances change. However, skills cannot be learned entirely from books; the opportunity to practise and receive constructive feedback on performance is essential.

CELL BIOLOGY

Cells consist of cytoplasm enclosed within a lipid sheath (the plasma membrane). The cytoplasm contains a variety of organelles (sub-cellular compartments enclosed within their own membranes) in a mixture of salts and organic compounds (the cytosol). These are held within an adaptive internal scaffold (the cytoskeleton) that radiates from the nucleus outwards to the cell surface (Fig. 2.1). Many cells have special functions and their size, shape and behaviour adapt to meet their physiological roles. Cells can be organized into tissues and organs in which the individual component cells are in contact and able to send and receive messages, both directly and indirectly. Coordinated cellular responses can be achieved through systemic signalling, e.g. via hormones.

CELL STRUCTURE

Cellular membranes

- **Lipid bilayers** separate the cell contents from the external environment and compartmentalize distinct cellular activities into organelles. These consist of a large variety of glycerophospholipids and sphingolipids.

Membrane lipids usually have two hydrophobic acyl chains linked via glycerol or serine, to polar hydrophilic head groups (Fig. 2.2). This amphiphilic nature, with a 'water-loving' head and a 'water-hating' tail, means that in aqueous solution membrane lipids self-associate into a tail-to-tail bilayer with their hydrophobic chains separated from the aqueous phase by their polar head groups.

- **Liposomes** are spheres enclosed within a lipid bilayer. This is the most energetically favourable form for membrane lipids in solution. These have been used clinically to deliver more hydrophilic cargo, such as drugs or DNA, to cells.
- **Plasma membranes** are more complicated than liposomes. Their lipids are organized asymmetrically in the bilayer. For example, the outer leaflet of the plasma membrane is enriched in phosphatidyl-choline (PC) and the sphingolipids, whereas the inner leaflet is enriched in phosphatidyl-serine (PS) and phosphatidyl-ethanolamine (PE). This arrangement is necessary in normal physiology and in disease, not just for barrier function. For example, PC is extracted from the outer-leaflet of the canalicular membrane of hepatocytes to form the

lipid/bile-salt micelles of bile. One of the sphingolipids, GM1-ganglioside, is the receptor for cholera toxin. The appearance of PS in the outer leaflet of the membrane is an early step in the apoptotic pathway and signals to macrophages to clear the dying cell, while PE, once cleaved by phospholipase, produces two signalling molecules as second messengers (see p. 25). Cholesterol is also an essential component of the

Figure 2.1 Diagrammatic representation of the cell, showing the major organelles and receptor activation, intracellular messengers, protein formation and secretion, endocytosis of large molecules and production of ATP.

plasma membrane and cannot be substituted by plant sterols, which have a subtly different shape. For this reason, the liver secretes plant sterols back into the gut.

Membrane proteins

Cells can absorb gases or small hydrophobic compounds directly across the plasma membrane by passive diffusion, but membrane proteins are required to take-up hydrophilic nutrients or secrete hydrophilic products, to mediate cell-cell communication and to respond to endocrine signals. Membrane proteins can be integral to the membrane (i.e. their protein chain traverses the membrane one or multiple times) or they can be anchored to the membrane by an acyl chain (Fig. 2.2).

The major classes are:

- **Membrane channel proteins** (Fig. 2.3): membrane proteins that form solute channels through the membrane can only work downhill and only to equilibrium. Solute actually moves down its electrochemical gradient, which is the combined force of the electric potential and the solute concentration gradient across the membrane. The bulk flow can be very high, the opening and closing of the channel can be regulated, and they can be selective for specific solutes. For example, the cystic fibrosis transmembrane regulator (CFTR; Fig. 2.22), the protein whose malfunction causes cystic fibrosis, is a chloride channel found on the apical surface of epithelial cells. CFTR functions to regulate the fluidity of the extra-epithelial mucous layer. When the channel opens, millions of negatively-charged chloride ions flow out of the cell down their electrochemical gradient. This induces positively-charged sodium ions to flow between the cells of the epithelium (via a paracellular pathway) to balance the electrical charge.

Figure 2.2 (a) Membrane lipid phosphatidyl-choline structure. The phospholipid structure is expanded to show its detail. (b) Cell membrane showing lipid structures and a selection of integral proteins such as receptors, G-proteins, channels, secondary messenger enzyme complexes and cell adhesion molecules.

Water follows the efflux of sodium chloride by osmosis, thus maintaining the fluidity of the mucus.

- **Transporters** (Fig. 2.3): in contrast to channels, transporters have a low capacity and work by binding solute on one side of the membrane which induces a conformational change that exposes the solute binding site on the other side of the membrane for release.
 - **Passive transporters** work without an energy source and can only transport downhill to equilibrium.
 - **Active transporters** use energy and can work uphill to concentrate a solute. Primary active transporters use the energy derived from binding and hydrolysis of ATP to drive the translocation cycle. ATP binding cassette (ABC) transporters are a major class of primary active transporters whose malfunction causes dozens of human diseases including a spectrum of liver, eye and skin diseases, bleeding disorders and

Figure 2.3 The difference between a transporter and a channel. (a) Transporters expose specific solute binding sites alternately on different sides of the membrane. They can function uphill if coupled to an energy source (active transport) or be downhill only (facilitated diffusion). They are low capacity. (b) Channels form a continuous pore through the membrane. They can be regulated and selective and only work downhill; bulk flow is high.

adrenoleukodystrophy. Secondary active pumps are driven by ion gradients which are themselves made and maintained by primary active pumps, thus primary and secondary active pumps often work in concert as illustrated for the transcellular uptake of glucose across the intestinal epithelia).

- **Receptors**: there are three major receptor categories: receptors that mediate endocytosis, anchorage receptors (e.g. integrins, see p. 23) and signalling receptors (see [cell signalling](#) p. 24). There are two forms of receptor-mediated endocytosis:
 - **Phagocytosis**: specialized phagocytic cells such as macrophages and neutrophils can engulf, or phagocytose ~20% of their surface in pursuit of large particles such as bacteria or apoptotic cells for digestion and recycling. Phagocytosis is only triggered when specific cell surface receptors – such as the macrophage Fc receptor – are occupied by their ligand.
 - **Pinocytosis** is a small-scale model of phagocytosis and occurs continually in all cells. Smaller molecular complexes, such as low-density lipoprotein (LDL) (Fig. 2.4a), are internalized during pinocytosis via clathrin-coated pits. The LDL receptor has a large extracellular domain which binds LDL to induce a conformational change in an intracellular domain of the receptor which allows it to bind clathrin from the cytoplasm. Clathrin bends the membrane to form a pit that pinches inwards to become an intracellular clathrin-coated vesicle. Loss of the clathrin coat can allow fusion with other intracellular organelles or vesicles (e.g. with lysosomes for degradation of the cargo), or the coat can be maintained for transcellular transport. Defects in each step of pinocytosis can lead to disease. For example, hypercholesterolaemia (p. 1035) can result from mutation to the LDL

receptor's extracellular domain that prevents LDL binding, but the most common LDL receptor mutation results in loss of the intracellular domain and prevents recruitment of clathrin.

Organelles

Cytoplasmic organelles

- **Endoplasmic reticulum (ER)** is an array of interconnecting tubules or flattened sacs (cisternae) that is contiguous with the outer nuclear membrane (Fig. 2.1). There are three types of ER:
 - **Rough ER** carries ribosomes on its cytosolic surface which synthesize proteins destined for secretion or membrane insertion.
 - **Smooth ER** is the site of lipid and sterol synthesis, and also of steroid and drug metabolism. With sodium pumps and channels in its membrane it is also a calcium store which is released for signalling.
 - **Sarcoplasmic reticulum** is a form of ER found in muscle, where release of calcium on excitation is necessary for muscle contraction.
- **Golgi apparatus** has flattened cisternae similar to those of the ER but arranged in a stack (Fig. 2.1). Vesicles that bud from the ER with cargo destined for secretion, for the plasma membrane or for other organelles, fuse with the Golgi stack. The proteins, lipids and sterols synthesized in the ER are exported to the Golgi apparatus to complete maturation (e.g. the final stages of membrane protein glycosylation occurs here). The mature products are then sorted into vesicles that bud from the Golgi for transport to their final destination (Fig. 2.4b,c). Mutation in the Golgi protein GMAP-210, with a probable role in tethering of the Golgi cisternae, causes achondrogenesis type 1A, where Golgi architecture is disrupted, particularly in bone cells.
- **Lysosomes** mature from vesicles (endosomes) that bud from the Golgi. They contain digestive enzymes such as lipases, proteases, nucleases and amylases that work in an acidic environment. The membrane of the lysosome therefore includes a proton ATPase pump to acidify the lumen of the organelle. Lysosomes fuse with phagocytotic vesicles to digest their contents. This is crucial to the function of macrophages and polymorphs (neutrophils and eosinophils) in killing and digesting infective agents, in tissue remodelling during development, and osteoclast remodelling of bone. Not surprisingly, many metabolic disorders result from impaired lysosomal function (p. 1040).
- **Peroxisomes** contain enzymes for the catabolism of long-chain fatty acids and other organic substrates like bile acids and D-amino acids. Hydrogen peroxide (H_2O_2), a by-product of these reactions, is a highly reactive oxidizing agent, so peroxisomes also contain catalase to detoxify the peroxide. Catalase can reduce H_2O_2 to water while oxidizing harmful phenols and alcohols thus beginning their detoxification. Peroxisome dysfunction can lead to rare metabolic disorders such as leukodystrophies and rhizomelic dwarfism.
- **Mitochondria** are the engines of the cell, providing energy in the form of ATP. Mitochondria can be small, discrete and few in number in cells with low energy

demand, or large and abundant in cells with a high energy demand like hepatocytes or muscle cells. The mitochondrion has its own genome encoding 13 proteins. The other proteins (~1000) required for mitochondrial function are encoded by the nuclear genome and imported into the mitochondrion. The mitochondrion has a double membrane surrounding a central matrix. The central matrix contains the enzymes for the Krebs cycle, which accepts the products of sugar and fatty acid catabolism and uses it to produce cofactors that donate their electrons into the electron transport chain of the inner membrane (see pp. 20, 31). The inner membrane is highly folded into cristae to increase its effective surface area. The protein complexes of the electron transport chain accept and donate electrons in redox reactions, releasing energy to efflux protons (H^+) into the inter-membrane space. ATP synthase, another integral membrane protein, uses this H^+ electrochemical gradient to drive formation of ATP. Mitochondria have many additional functions, including roles in apoptosis (see p. 32) and supply of substrates for biosynthesis. Mitochondria are also necessary for the synthesis of porphyrin, deficiency of which causes a range of diseases collectively called porphyrias (p. 1043).

Nucleus

The most prominent cellular organelle, the nucleus, has a double membrane (the outer membrane is continuous with the ER) enclosing the human genome. The double membrane contains nuclear pores through which gene regulatory proteins, transcription factors and RNA that has been transcribed from the DNA, are transported. The nuclear matrix is highly organized. Microscopically dense regions of heterochromatin represent highly compacted chromosomal DNA which tends to be transcriptionally repressed. Lighter regions of euchromatin contain extended chromosomes which tend to be transcriptionally active. The most prominent nuclear compartment, the nucleolus, is where ribosomal RNA (rRNA) is synthesized and ribosomal subunits are assembled.

The cytoskeleton

A complex network of structural proteins regulates the shape, strength and movement of the cell, and the traffic of internal organelles and vesicles. The major components are microtubules, intermediate filaments and microfilaments.

- **Microtubules** (20–25 nm diameter) are polymers of α and β tubulin. These tubular structures resist bending and stretching, and are polar with plus and minus ends. They emanate from the microtubule organizing centre (MTOC), a complex of centrioles, γ -tubulin and other proteins, with their plus ends extending into the cell. At their plus ends repeated cycles of assembly and disassembly permit rapid changes in length. Microtubules form a 'highway', transporting organelles and vesicles through the cytoplasm. The two major microtubule-associated motor proteins (kinesin and dynein) allow movement of cargo to the plus and minus ends, respectively. During cell division the MTOC forms the mitotic spindle (see p. 28). Drugs that disrupt microtubule assembly (e.g. colchicine and vinca alkaloids) or stabilize microtubules (taxanes) preferentially kill dividing cells by preventing mitosis.
- **Intermediate filaments** (~10 nm) form a network around the nucleus extending to the periphery of the cell. They make cell-to-cell contacts with adjacent

cells via desmosomes, and with basement matrix via hemidesmosomes (Fig. 2.5; see also Fig. 24.27). Their function appears to be structural integrity; they are prominent in cellular tissues under stress and their disruption in genetic disease can cause structural defects or cell collapse. More than 40 different types of proteins polymerize to form intermediate filaments specific to particular cell types. For example keratin intermediate fibres are only found in epithelial cells whilst vimentin is in mesothelial (fibroblastic) cells. However, lamin intermediate filaments form the nuclear membrane skeleton in most cells.

- **Microfilaments** (3–6 nm) are polymers of actin, one of the most abundant proteins in all cells. The actin microfilament network controls cell shape, prevents cellular deformation, is involved in cell–cell and cell–matrix adhesion, in cell movements such as crawling and cytokinesis (cell division), and in intracellular vesicle transport. Bundles of actin filaments form the structural core of cellular protrusions such as microvilli, lamellipodia and filopodia (see below). Actin microfilament bundles within the cell can associate with myosin II to form contractile stress fibres, similar to muscle sarcomeres. Stress fibres are often found as circumferential belts around the apical surfaces of epithelial cells where cells associate with adjacent cells via adherens junctions, permitting reaction to external stresses as a cellular sheet. Stress fibres also form where actin interacts via accessory proteins with the extracellular matrix at sites of focal adhesion (see Fig. 2.8c). This occurs during cell movements during inflammation, wound healing and metastasis. During cytokinesis actin-myosin II bundles form the contractile ring separating dividing cells. Like microtubules, microfilaments are polar, so can be used to transport secretory vesicles, endosomes and mitochondria, powered by motor proteins, including myosin I and V.

Cell shape and motility

The cytoskeleton determines cell shape and surface structures.

Microvilli. The apical surface of some epithelial cells is covered in tiny microvilli (~1 µm long) forming a brush border of thousands of small finger-like projections of the plasma membrane that increase the surface area for uptake or efflux (Fig. 2.6). At their core are 20–30 cross-linked actin microfilaments.

Figure 2.6 Cilia and microvilli in trachea. (a) Scanning electron microscopy image of longer cilia bearing cells with adjacent microvilli-bearing cells. (b) Transmission electron microscope image of section. (Courtesy of Louisa Howard, Dartmouth EM Facility.)

Motile cilia are also fine, finger-like protrusions but these are longer (~10–20 µm long) (Fig. 2.6). At their core is an axoneme, a bundle of nine cross-linked tubulin microtubule doublets surrounding a central pair. The action of the motor domain dynein serves to bend the cilium. Neighbouring cilia tend to beat in unison generating waves of motion that move fluid over the cell surface in the gut and airways (see Fig. 15.9), and also in the fallopian tubes.

Non-motile or primary cilia. Most cells also have a single **primary cilium**. These cilia have a variant axoneme with no central pair of microtubules and while they have dynein they are non-motile (the dynein is used to traffic cargo along the axoneme). Primary cilia are used for signalling during development and in the adult. Other related non-motile cilia are found in specialized cells, e.g. in the photoreceptors of the retina, the sensory neurones of the olfactory system, and in the sensory hair cells of the cochlea. A range of human **ciliopathies** (Fig. 2.7) have been described with pleiotropic symptoms depending on which cilia are affected. These include polycystic kidney disease, Bardet–Biedl syndrome (p. 1007), Joubert’s syndrome and Ellis–van Creveld syndrome.

Flagella. The single **flagellum** found on sperm is structurally related to cilia but is longer (~40 µm) and has a whip-like motion.

Cell motility is essential during development and in the adult when macrophages migrate to sites of infection, keratinocytes migrate to close wounds, osteoclasts and osteoblasts tunnel into and remodel bone, and fibroblasts migrate to sites of injury to repair the extracellular matrix. Most cell motility in the adult human takes the form of cell crawling which is dependent on remodelling of the actin cytoskeleton. How the actin cytoskeleton is remodelled determines the mode of migration:

- **Filopodia:** if remodelled essentially in one dimension into a long actin filament, the leading edge of the plasma membrane is pushed forward as spikes, similar to long thin villi.
- **Lamellipodia:** if remodelled in two dimensions to form a network of cross-linked actin microfilaments, a broad flat skirt or lamellipodium is formed.
- **Pseudopodia:** are more three-dimensional projections as the actin cytoskeleton is remodelled into a gel-like lattice.

Microfilament (actin) cytoskeleton adhesion belt in polarized epithelial cells.

Figure 2.7 Structure of a cilium showing ciliopathy proteins and intraflagellar transport (IFT). Some single-gene ciliopathies are shown along with their gene products situated in the cilia centrosome complex (CCC). Receptors on cilia receive external cell signals which are processed via sonic hedgehog (SHH) and Wnt pathways. The gene mutation can act during morphogenesis (e.g. Meckel's syndrome) or during tissue maintenance and repair leading to degenerative disorders. The IFT system transports axoneme and membrane compounds in raft macromolecular particles (IFT cargo and complex). Retrograde transport occurs via cytoplasmic dynein. NPHP1, nephronophthisis type 1; TRPR1 and 2, polycystin 1 and 2. (Adapted from Hildebrandt F, Benzing T, Katsanis N. *Ciliopathies*. New England Journal of Medicine 2011; 364:1533–1543.)

Movement. A similar mechanism involving the coordinated remodelling of the cytoskeleton and the formation and release of cell adhesions underlies all three modes of migration. Essentially, actin is polymerized at the leading edge extending the plasma membrane forward. New adhesions are formed with the substratum (cells and/or extracellular matrix) at the leading edge to provide purchase. Release of attachments and depolymerization of the actin filaments at the trailing edge then allows the cell to move forward. Myosin and myosin motor proteins may also be involved at the trailing edge providing the tractive force to pull the cell body forward. The complex coordination of these processes is controlled via signalling pathways involving members of the Rho protein family of GTPases (see p. 21). Key signalling targets are the WASp family of proteins which stimulate actin polymerization. The significance of cell motility in humans is illustrated by mutation of the WASp expressed in blood cell lineages, which causes Wiskott–Aldrich syndrome (p. 66), and is characterized by severe immunodeficiency and thrombocytopenia (platelet deficiency).

THE CELL AND ITS ENVIRONMENT

Most cells differentiate or specialize to perform particular functions within tissues where they interact with the extracellular matrix (ECM) or other cells. The major tissue types are

epithelia and connective tissues as well as muscle and neural tissue:

- **Epithelial tissues** comprise layers of cells held tightly together by intercellular junctions and are usually separated from underlying tissue by specialized ECM called basal lamina. Epithelia cover surfaces (e.g. epidermis, tongue surface) and line passageways (airways, digestive tract, blood vessels), providing protection and regulating absorption and secretion.
- **Connective tissues** provide support to other tissues and give organs shape. They comprise cells (fibroblasts) embedded within ECM such as the matrix of bone, dermis of skin and the fluid matrix of blood.

Extracellular matrix

The ECM is the gel matrix outside the cell, usually secreted by fibroblasts. ECM determines tissue properties, e.g. in bone it is calcified; in tendons it is tough and rope-like; and in neural tissue it is almost absent. However, ECM is more than just a support matrix. It affects cell shape, migration, cell-cell communication and signalling, proliferation and survival.

The gel or ground substance of the ECM is made from polysaccharides (glycosaminoglycans or GAGs), usually bound to proteins to form proteoglycans (p. 494). These are a diverse group of molecules conferring different matrix properties in different tissues. They form hydrated gels which can resist compression yet permit diffusion of metabolites and signalling molecules.

- **Hyaluronan**, a very large hydrated GAG, is secreted into the joint space in synovial joints (p. 493), where it aids lubrication and helps reduce compressive forces.
- **Aggrecan**, a very large proteoglycan, forms part of the articular cartilage of joints (p. 494) also contributing to compression resistance.
- **Decorin** is a much smaller proteoglycan from loose connective tissue of skin with both structural and signalling function (through binding and regulating growth factor activity).

Fibrous proteins of ECM (p. 495) include collagens and tropoelastin, which polymerize into collagen and elastin fibres, and fibronectin which is insoluble in many tissues but soluble in plasma. Collagen provides tensile strength, elastin confers elasticity, while the widely distributed fibronectin adheres to both cells and ECM, and thus positions cells within the ECM. Collagens, the most abundant proteins in the body, are widely distributed and play a structural role in skin and bone, where collagen defects and disorders often manifest. Elastin fibres are abundant in arteries, lung and skin. Elastic fibres have a fibrillin sheath and fibrillin mutations underlie Marfan's syndrome (p. 760). The ECM can be degraded and remodelled by proteins of the matrix metalloproteinase (MMP) family. These are needed for angiogenesis and morphogenesis and are also involved in the pathophysiology of cancer, cirrhosis and arthritis.

Basal lamina or basement membrane (*lamina propria*) is a specialized form of ECM, which separates cells from underlying tissue and provides a supportive, anchoring and protective role. Basal lamina can also act as molecular filters (e.g. glomerular filtration barrier, p. 636) and mediate signalling between adjacent tissues (e.g. epidermal-dermal signalling in skin). Type IV collagen, heparan sulphate proteoglycan, laminin and nidogen are key basal lamina proteins. Inherited abnormalities in these proteins cause skin blistering diseases (see Fig. 24.27). Breach of the basal lamina by invading

cancer cells is a key stage in progression of epithelial carcinoma in situ to a malignant carcinoma.

Cell-cell adhesion

Cells need to interact directly for barrier function, tissue strength and to communicate. This is mediated by several types of proteins that form junctions between cells.

Cell-cell adhesion proteins (Fig. 2.8a)

As well as adhesion via multiprotein junctions, intercellular adhesion is achieved by individual transmembrane proteins.

- **Immunoglobulin-like cell adhesion molecules (iCAMs or CAMs)** (Fig. 2.8a) are structurally related to antibodies. The neural cell adhesion molecule (N-CAM) is found predominantly in the nervous system. It mediates a homophilic (like-like) adhesion. When bound to an identical molecule on another cell, N-CAM can also associate laterally with a fibroblast growth factor receptor and stimulate its tyrosine kinase activity to induce neurite growth thus triggering cellular responses by indirect activation of the recipient.
- **Selectins.** Unlike most adhesion molecules which bind to other proteins, the selectins interact with carbohydrate ligands or **mucin complexes** on leucocytes and endothelial cells (vascular and haematological systems). *Leucocyte-selectin* (CD62L) mediates the homing of lymphocytes to lymph nodes. *Endothelial-selectin* (CD62E) is expressed after activation by inflammatory cytokines; the small basal amount of E-selectin in many vascular beds appears to be

necessary for the migration of leucocytes. *Platelet-selectin* (CD62P) is stored in the alpha granules of platelets and the Weibel–Palade bodies of endothelial cells, but it moves rapidly to the plasma membrane upon stimulation of these cells. All three selectins play a part in leucocyte rolling (p. 63).

- **Integrins** are membrane glycoproteins with α and β subunits which exist as active and inactive forms. The amino acid sequence arginine–glycine–aspartic acid (RGD) is a potent recognition system for integrin binding

Focal adhesion junctions between adjacent cells

See Figure 2.8b.

Tight junctions (zonula occludens)

These are mediated by the integral membrane proteins, claudins and occludins; they hold cells together. They form at the top (apical) side of epithelial cells including intestinal, skin and kidney cells, and endothelial cells of blood vessels (Fig. 2.8) to provide a regulated barrier to the movement of ions and solutes through the epithelia or endothelia but also between cells (paracellular transport). Tight junctions also confer polarity to cells by acting as a gate between the apical and the baso-lateral membranes, preventing diffusion of membrane lipids and proteins. Twenty-four **claudins** (the protein in the junction) are differentially expressed in different cell types to regulate paracellular transport. For example, changes in claudin expression in the kidney nephron correlate with permeability changes. Mutations in claudins 16 (previously named parcellin-1) and 19, expressed in the thick ascending limb in the loop of Henle in the kidney, cause an

inherited renal disorder, familial hypomagnesaemia with hypercalciuria and nephrocalcinosis (FHHNC; p. 657).

Gap junctions

Gap junctions (Fig. 2.8) allow low molecular weight substances to pass directly between cells, permitting metabolic and electric coupling (e.g. in cardiomyocytes). Protein channels made of six **connexin** proteins (as well as **claudins** and **occludins**) are aligned between adjacent cells and allow the passage of solutes up to 1000 kDa (e.g. amino acids, sugars, ions, chemical messengers). The channels are regulated by many factors such as intracellular Ca^{2+} , pH, voltage. Gap junctions form in almost all interacting cells, but connexin family members are differentially expressed. Mutant connexins cause many inherited disorders, such as the X-linked form of Charcot–Marie–Tooth disease (GJB1; p. 1147) and are also a major cause of genetic hearing loss (GJB2).

Adherens junctions

Adherens junctions are multiprotein intercellular adhesive structures, prominent in epithelial tissues (Fig. 2.8b). They attach principally to actin microfilaments inside the cell with the aid of multiple additional proteins, and also attach and stabilize microtubules. At the apical sides of epithelial cells a prominent type of adherens junction, the *zonula adherens*, attaches to the circumferential actin stress fibres. The *fascia adherens* in cardiac muscle is also an adherens junction. Transmembrane proteins of the cadherin family provide the adhesion through interaction of their extracellular domains. Downregulation of cadherins is a feature of cancer progression in many cells.

Desmosomes (macula adherens)

Desmosomes provide strong attachment between cells and are prominent in tissues subject to stress such as skin and cardiac muscle (see Fig. 2.5, Fig. 2.8b and Fig. 2.4.1). Like adherens junctions, they are multiprotein complexes, where adhesion is provided by transmembrane cadherin proteins, desmogleins and desmocollins. However, within the cell desmosomes interact principally with intermediate filaments rather than microfilaments and microtubules. Germline mutations in genes encoding desmosomes are a cause of cardiomyopathy with/without cutaneous features and in *pemphigus vulgaris* and *pemphigus foliaceus* (p. 1222).

Basement membrane adhesion

Cells adhere (Fig. 2.8c) to non-basal lamina ECM via secreted proteins such as fibronectin and collagen, and to basal lamina proteins via focal adhesion and hemidesmosome multiprotein complexes (e.g. keratin or vimentin). Here, **integrins** replace cadherins as surface adhesion molecules as the key adhesive proteins. Integrins are transmembrane sensors or receptors, which change shape upon binding to ECM, a process called ‘outside-in’ signalling. Inside the cell, integrins interact with the cytoskeleton and a complex array of over 150 proteins that influence intracellular signalling pathways affecting proliferation, survival, shape, mobility and gene expression.

- **Outside-in signalling:** forms the basis for anoikis or apoptotic death, such as occurs in cancer cells that inappropriately lose cell-substratum adhesion.
- **Inside-out signalling:** intracellular changes can also be communicated extracellularly via integrins whereby

intracellular changes cause integrins to change from an inactive to an actively adhesive conformation. This ‘inside-out’ signalling occurs when platelet integrins glycoprotein IIb–IIIa (GPIIb–IIIa) are activated to bind fibrinogen at sites of vessel injury, resulting in platelet aggregation (p. 415 and Fig. 8.41).

Defective integrins are associated with many immunological and clotting disorders such as Bernard–Soulier syndrome and Glanzmann’s thrombasthenia (p. 420).

CELLULAR MECHANISMS**Cell signalling**

Signalling or communication between cells is often via extracellular molecules or ligands which can be proteins (e.g. hormones, growth factors), small molecules (e.g. lipid-soluble steroid hormones such as oestrogen and testosterone) or dissolved gases such as nitric oxide. The signal is usually received by membrane protein receptors, although some signals such as steroid hormones, enter the target cell where they interact with intracellular receptors (Fig. 2.9). Some signalling, especially in the immune system, relies on cell–cell contact, where the signalling molecule (ligand) and receptor are on adjacent cells.

Receptors transduce signals across the membrane to an intracellular pathway or second messengers to change cell behaviour, often ultimately affecting gene expression (Figs 2.9, 2.10). The membrane-bound receptors fall into three main groups based on downstream signalling pathways:

- **Ion channel linked receptors** (voltage or ligand activated ion channels; see Fig. 2.3). At synaptic junctions between neurones (Fig. 22.1), these receptors open in response to neurotransmitters such as glutamate, epinephrine (adrenaline) or acetylcholine to cause a rapid depolarization of the membrane.
- **G-protein-linked receptors** such as the odorant and light (opsin) family of receptors belong to a large family of seven-pass transmembrane proteins (see Figs 2.2 and 2.9). On activation by ligand G-protein-linked receptors bind a GTP-binding protein (G-protein), which activates adjacent enzyme complexes or ion channels (Figs 2.9 and 22.1). The adjacent enzymes can be adenylylase (see below).
- **Enzyme-linked receptors** (Figs 2.2 and 2.9) typically have an extracellular ligand-binding domain, a single transmembrane-spanning region, and a cytoplasmic domain that has intrinsic enzyme activity or which will bind and activate other membrane-bound or cytoplasmic enzyme complexes. This group of receptors is highly variable but many have kinase activity or associate with kinases, which act by phosphorylating substrate proteins usually on a tyrosine (e.g. the platelet-derived growth factor (PDGF) receptor) or a serine/threonine (e.g. the transforming growth factor- β (TGF- β) receptor).

Signal transduction

Signal transduction from the receptor to the site of action in the cell is mediated by small signalling molecules called second messengers, or by signalling proteins (Fig. 2.9). Changes to activity of signalling proteins by acquired

Figure 2.9 Cell signalling. (i) G-protein receptor binds ligand (e.g. hormone) and activates G-protein complex. The G-protein complex can activate three different secondary messengers: (a) cAMP generation; (b) inositol 1,4,5-trisphosphate (IP₃) and release of Ca²⁺; (c) diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation. (ii) Enzyme-linked receptors often dimerize upon ligand binding. Intracellular domains cross-phosphorylate and link to the phosphorylation cascades such as the MAP kinase cascade, via molecules such as Ras. (iii) Lipid-soluble molecules, e.g. steroids, pass through the cell membrane and bind to cytoplasmic receptors, which enter the nucleus and bind directly to DNA.

mutation occur in cancer, and many anti-cancer drugs target signalling pathways. For example, the **Hedgehog** pathway is involved in human development, tissue repair and cancer (Fig. 2.10). Inhibitors of this pathway are being developed for therapeutic interventions. The **Wnt** pathway is also involved in bone formation (p. 550).

- **Second messengers** include cAMP and lipid-derived inositol triphosphate (IP₃) and diacylglycerol (Fig. 2.9). These molecules diffuse from the receptor to bind and change the activity of downstream proteins propagating the signal. cAMP triggers a protein signalling cascade by activating a cAMP-dependent protein kinase. Diacylglycerol activates protein kinase C while IP₃ mobilizes calcium from intracellular stores (e.g. from the ER; Fig. 14.9).
- **G-proteins** or GTP-binding proteins are signalling proteins which switch between an active state when GTP is bound and an inactive state when bound to GDP. The most well-known members are the Ras superfamily, comprising Ras, Rho, Rab, Arf and Ran families. Activation of Ras members by somatic mutation is found in ~33% of human cancers. Ras members are often bound downstream of tyrosine kinase receptors, where they transmit signals by activating a cascade of downstream protein kinase activity (Fig. 2.9). Ras signalling molecules have roles in

many cellular activities, including regulation of cell cycle, intracellular transport, and apoptosis.

- **Kinase and phosphatase signalling proteins** are enzymes that phosphorylate or dephosphorylate residues on downstream proteins to alter their activity. Chains of kinase activity (phosphorylation cascades) consisting of sequential phosphorylation of proteins can transduce signals from the membrane receptor to the site of action in the cell. The tyrosine kinase receptors phosphorylate each other when ligand binding brings the intracellular receptor components into close proximity (see Fig. 2.9). The inner membrane and cytoplasmic targets of these activated receptor complexes are *ras*, protein kinase C and ultimately the MAP (mitogen-activated protein) kinase, Janus-Stat pathways or phosphorylation of IκB causing it to release its DNA-binding protein, nuclear factor kappa B (NFκB). For example, activated Ras binds and activates the kinase Raf, the first of a set of three mitogen-activated protein (MAP) kinases, which transmit signals by successive phosphorylation of target proteins which can ultimately effect transcription (Fig. 2.9). Kinases and phosphatases are frequently mutated in cancers. Somatic mutations in one Raf member, B-Raf, occur in ~60% of malignant melanomas (usually the mutation V600E) and are common in other cancers (p. 1225).

Cell signalling information:

<http://www.biochemj.org/csb/>

Figure 2.10 Signal transduction showing the Hedgehog and Wnt signalling pathways. (a) Wnt signalling has three pathways: the canonical (β catenin), Wnt/ Ca^{2+} and planar cell polarity pathways. Wnt binds to the frizzled protein and then dishevelled activity via other pathways inhibits phosphorylation of β catenin. This alters gene transcription. TCF, T-cell factor. **(b)** Hedgehog ligand (Hh) binds to a 12-transmembrane protein receptor Patched (Ptc). This acts as an inhibitor of smoothened (Smo), another transmembrane protein related to the Frizzled family of Wnt receptors. In the presence of Hh the inhibitory effects of Ptc on Smo are removed and Smo is phosphorylated by protein kinase A and other kinases. This prevents cleavage of Ci which enters the nucleus inducing the transcription of Hh target genes. Ci, cubitus interruptus, a zinc finger protein.

Nuclear control

DNA and RNA structure

Hereditary information is contained in the sequence of the building blocks of double-stranded deoxyribonucleic acid (DNA) (Fig. 2.11). Each strand of DNA is made up of a deoxyribose-phosphate backbone and a series of purine (adenine (A) and guanine (G)) and pyrimidine (thymine (T) and cytosine (C)) bases, and because of the way the sugar phosphate backbone is chemically coupled, each strand has a polarity with a phosphate at one end (the 5' end) and a hydroxyl at the other (the 3' end). The two strands of DNA are held together by hydrogen bonds between the bases. A can only pair with T, and G can only pair with C, therefore each strand is the antiparallel complement of the other (Fig. 2.11b). This is key to DNA replication because each strand can be used as a template to synthesize the other.

The two strands twist to form a double helix with a major and a minor groove, and the large stretches of helical DNA are coiled around histone proteins to form nucleosomes (Fig. 2.11c). They can be condensed further into the chromosomes that can be visualized by light microscopy at metaphase (see below; Fig. 2.11, Fig. 2.19).

To express the information in the genome, cells first transcribe the code into the single strand ribonucleic acid (RNA). RNA is similar to DNA in that it comprises four bases A, G

and C but with uracil (U) instead of T, and a sugar phosphate backbone with ribose instead of deoxyribose. Several types of RNA are made by the cell. Messenger RNA (mRNA) codes for proteins that are translated on ribosomes. Ribosomal RNA (rRNA) is a key catalytic component of the ribosome and amino acids are delivered to the nascent peptide chain on transfer RNA (tRNA) molecules. There are also a variety of RNAs that regulate gene expression or RNA processing. These include microRNA (miRNA) and small interfering RNA (siRNA) (see p. 27) that typically bind to a subset of mRNAs and inhibit their translation, or initiate their degradation, respectively. Other non-coding RNAs are involved in X-inactivation and telomere maintenance or RNA splicing and maturation.

DNA transcription

A gene is a length of DNA (usually 20–40 kb but the muscle protein dystrophin is encoded by 2.4 Mb) that contains the codes for a polypeptide sequence. Three adjacent nucleotides (a codon) specify a particular amino acid, such as AGA for arginine. There are only 20 common amino acids, but 64 possible codon combinations make up the genetic code. This redundancy means that most amino acids are encoded by more than one triplet and other codons are used as signals for initiating or terminating polypeptide-chain synthesis.

RNA is transcribed from the DNA template by an enzyme complex of more than one hundred proteins including RNA polymerase, transcription factors and enhancers. Promoter regions upstream of the gene dictate the start point and direction of transcription. The complex binds to the promoter region, the nucleosomes are remodelled to allow access, and a DNA helicase unwinds the double helix. RNA, like DNA, is synthesized in the 5' to 3' direction as ribonucleotides are added to the growing 3' end of a nascent transcript. RNA polymerase does this by base-pairing the ribonucleotides to the DNA template strand running in the 3' to 5' direction. Messenger RNA is modified as it is synthesized (Fig. 2.12). It is capped at the 5' end with a modified guanine that is required for efficient processing of the mRNA and efficient translation, and introns are spliced from the nascent chain. Finally, the 3' of the mRNA is modified with up to 200 A nucleotides by the enzyme poly-A polymerase. This 3' poly-A tail is essential for nuclear export (through the nuclear pores), stability and efficient translation into protein by the ribosome.

Human protein coding sequences (exons) are interrupted by intervening sequences that are non-coding (introns) at multiple positions (Fig. 2.12). These have to be spliced from the nascent message in the nucleus by an RNA/protein complex called a spliceosome. Differential splicing describes the process by which two or more introns and their intervening exons are spliced from the mRNA. This contributes significantly to the complexity of the human transcriptome as proteins translated from these messages lack particular domains. This exon skipping can produce different protein activities.

Control of gene expression

The genome of all cells in the body encodes the same genetic information, yet different cell types express a very different subset of proteins and respond to external signals to switch on a new set of genes or to switch off a pathway. Gene expression can be controlled at many steps from transcription to protein degradation. However, for many genes transcription is the key point of regulation. This is controlled primarily

Figure 2.11 DNA and its structural relationship to human chromosomes. (a) A polynucleotide strand with the position of the nucleic bases indicated. Individual nucleotides form a polymer linked via the deoxyribose sugars. The 5' carbon of the heterocyclic sugar structure is coupled to a phosphate molecule. The 3' carbon couples to the phosphate on the 5' carbon of ribose of the next nucleotide forming the sugar-phosphate backbone of the nucleic acid. The 5' to 3' linkage gives orientation to a sequence of DNA. (b) Double-stranded DNA. The two strands of DNA are held together by hydrogen bonds between the bases. T always pairs with A, and G with C. The orientation of the complementary single strands of DNA (ssDNA) is thus complementary and anti-parallel, i.e. one will be 5' to 3' while the partner will be 3' to 5'. The helical 3D structure has major and minor grooves and a complete turn of the helix contains 12 base-pairs. These grooves are structurally important, as DNA-binding proteins predominantly interact with the major grooves. (c) Supercoiling of DNA. The large stretches of helical DNA are coiled to form nucleosomes and further condensed into the chromosomes that can be seen at metaphase. DNA is first packaged by winding around nuclear proteins – histones – every 180 bp. This can then be coiled and supercoiled to compact nucleosomes and eventually visible chromosomes. (d) At the end of the metaphase DNA replication results in a twin chromosome joined at the centromere. This picture shows the chromosome, its relationship to supercoiling, and the positions of structural regions: centromeres, telomeres and sites where the double chromosome can split. Chromosomes are assigned a number or X or Y, plus short arm (p) or long arm (q). The region or subregion is defined by the transverse light and dark bands observed when staining with Giemsa (hence G-banding) or quinacrine and numbered from the centromere outwards. *Chromosome constitution* = chromosome number + sex chromosomes + abnormality; e.g. 46XX = normal female; 47XX+21 = Down's syndrome; (trisomy 21) 46XYt (2;19) (p21; p12) = male with a normal number of chromosomes but a translocation between chromosome 2 and 19 with breakages at short-arm bands 21 and 12 of the respective chromosomes.

by proteins which bind to short sequences within the promoter regions that either repress or activate transcription, or to more distant sequences where proteins bind to enhance expression. These transcription factors and enhancers are often the end points of signalling pathways that transduce extracellular signals to changes in gene expression (Fig. 2.9).

Often this involves the translocation of an activated factor from the cytoplasm to the nucleus. In the nucleus the DNA binding proteins recognize the shape and position of hydrogen bond acceptor and donor groups within the major and minor grooves of the double helix (i.e. the double helix does not need to be unwound). There are several classes of DNA binding protein that differ in the protein structural motif that allows them to interact with the double helix. These primarily include **helix-turn-helix**, **zinc finger** and **leucine zipper** motifs, although protein **loops** and **β -sheets** are used by some proteins. More permanent control of gene expression patterns can be achieved epigenetically. These are modifications (typically methylation and/or acetylation) of the DNA, or the histones of the nucleosome, that silence genes. Epigenetic modification is also heritable meaning that a dividing liver cell, for example, can give rise to two daughter cells with the same epigenetic signals such that they express the appropriate transcriptome for a liver cell. Epigenetic change forms the basis of genetic imprinting (see p. 42).

Most of the genome is transcribed but only a minority of transcripts encode proteins (see *Human Genetics*, p. 34). The non-coding RNAs (ncRNAs) include a group that regulate

gene expression (see *DNA and RNA structure*). miRNAs and siRNAs are short ncRNAs (19–29 bp) that are known to regulate expression of approximately 30% of genes by degradation of transcripts or repression of protein synthesis. With further annotation of the genome a growing range of additional regulatory ncRNA classes are being identified, many of which control gene expression by epigenetic mechanisms.

The cell cycle and mitosis

The cell duplication cycle has four phases, G1, S, G2 and mitosis (Fig. 2.13), and takes about 20–24 hours to complete for a rapidly dividing adult cell. G1, S and G2 are collectively known as interphase during which the cells double in mass (the two gap phases are used for growth) and duplicate their 46 chromosomes (S phase). **Mitosis** describes, in four sub-phases (prophase, metaphase, anaphase and telophase), the process of chromosome separation and nuclear division before cytokinesis (division of the cytoplasm into two daughter cells).

Synthesis phase; DNA replication

DNA synthesis is initiated simultaneously at multiple replication forks in the genome and is catalysed by a multi-enzyme complex. The key components of the replication machinery are:

Figure 2.12 Transcription and translation (DNA to RNA to protein). RNA polymerase creates an RNA copy of the DNA gene sequence. **This primary transcript is processed: capping of the 5' free end of the mRNA precursor involves the addition of an inverted guanine residue to the 5' terminal which is subsequently methylated, forming a 7-methylguanosine residue. The 3' end of mRNA defined by the sequence AAUAAA acts as a cleavage signal for an endonuclease, which cleaves the growing transcript about 20 bp downstream from the signal. The 3' end is further processed by a poly-A polymerase which adds adenosine residues to the 3' end, forming a poly-A tail (polyadenylation).** **Splicing out of the introns then produces the mature mRNA, which is trafficked out of the nucleus via nuclear pores.** Ribosomal subunits assemble on the mRNA moving along 5' to 3'. **With the transport of amino acids to their active sites by specific tRNAs, the complex translates the code, producing the peptide sequence.**

- **DNA helicase** which hydrolyses ATP to unwind the double helix and expose each strand as a template for replication. The two strands are antiparallel, and because DNA can only be extended by addition of nucleotide triphosphates to the 3'-hydroxyl end of the growing chain, replication of each strand must be treated differently. For one strand, called the leading template strand, the replication fork is moving in a 3' to 5' direction along the template, meaning that the newly synthesized strand is being synthesized in a 5' to 3' direction.
- **DNA primase** synthesizes a short (~10 nucleotide) RNA molecule annealed to the DNA template which acts as a primer for DNA polymerase.

Figure 2.13 The cell cycle. Cells are stimulated to leave non-cycle G0 to enter G1 phase by growth factors. During G1, transcription of the DNA synthesis molecules occurs. Rb is a 'checkpoint' (inhibition molecule) between G1 and S phases and must be removed for the cycle to continue. This is achieved by the action of the cyclin-dependent kinase produced during G1. During the S phase, any DNA defects will be detected and p53 will halt the cycle (see p. 46). Following DNA synthesis (S phase), cells enter G2, a preparation phase for cell division. Mitosis takes place in the M phase. The new daughter cells can now either enter G0 and differentiate into specialized cells, or re-enter the cell cycle.

- **DNA polymerase** extends the primer by adding nucleotides to the 3'-end. For the leading template strand, the RNA primer is only required to initiate synthesis once and polymerization continues just behind the replication fork. For the antiparallel strand, the template is being exposed in a 5' to 3' direction and DNA primase is required to synthesize RNA primers every ~200 nucleotides to prime DNA synthesis in the opposite direction to the replication fork. To allow for this, the synthesis against this template is delayed and so it is called the lagging strand and requires more of the strand to be exposed for DNA primase and DNA polymerase to engage.
- **Single-strand DNA binding proteins** are required to bind to the exposed single-strand DNA and stabilize it in single-strand form. Once DNA polymerase has extended the new strand to cover the 200 nucleotides between each RNA primer (the single-strand RNA/DNA hybrid is called an **Okazaki fragment**).
 - **RNAase H** removes the RNA primer from the preceding Okazaki fragment, DNA polymerase extends the new strand over the gap.
 - **DNA ligase** joins the two DNA fragments together.

The phases of mitosis

Prophase. The two sister chromatids (the replicated chromosomes held together by a protein complex called a kinetochore) condense in the nucleus. The two centrosomes between which the microtubules of the mitotic spindle will

form move apart in the cytoplasm. At the end of prophase (sometimes known as prometaphase), the nuclear membrane breaks down and the spindle microtubules attach to the kinetochores.

Metaphase. The chromosomes are aligned on a central plane with the two centrosomes at opposite poles. The sister chromatids are attached to microtubules from different centrosomes via the kinetochore.

Anaphase. The sister chromatids separate and are pulled in opposite directions as the microtubules shorten towards their respective spindle poles.

Telophase. Each set of daughter chromosomes are held at a spindle pole and the nuclear envelope reforms around the genome of each new daughter cell.

Cytokinesis

Binary fission of the cytoplasm begins in telophase before the completion of mitosis with the appearance of a ring of actin and myosin filaments around the equator of the cell. Cytokinesis is completed as the ring contracts to create a cleavage furrow and separate the two daughter cells.

Control of the cell cycle and checkpoints

Cells can exit the cell cycle and become quiescent. Indeed most terminally-differentiated adult cells are in a phase termed G0 in which the cycling machinery is switched off. In some cell types the switch is irreversible (e.g. in neurones), but others, like hepatocytes, retain the ability to re-enter the cell cycle and proliferate. This gives the liver a significant ability to regenerate following damage.

Cyclin-dependent kinases (Cdks), Retinoblastoma (Rb) and p53

Progression through the cell cycle is tightly controlled and punctuated by three key checkpoints when the cell interprets environmental and cellular signals to determine whether it is appropriate or safe to proceed (Fig. 2.13). The switches that allow progression beyond these checkpoints are a family of small protein complexes called cyclin-dependent kinases (Cdks) that phosphorylate serines or threonines in key target proteins at each stage. It is the regulatory cyclin subunit of the Cdks that oscillates during the cell cycle (the actual kinase domain may be present throughout but only activated by the transient expression of its cognate cyclin).

Checkpoints

The restriction point (G1 checkpoint)

The restriction point works to ensure the cell cycle does not progress into S-phase unless growth conditions are favourable and the genomic DNA is undamaged. The cyclin-cdk complexes active early in S-phase are denoted S-Cdk (cyclin A with Cdk1 or Cdk2).

S-Cdks have two roles:

- to phosphorylate their target proteins to initiate helix unwinding of the DNA at origins of replication allowing the replication complex to begin DNA synthesis
- to prevent re-initiation at the same origin during the same cell cycle (because it would be deleterious to copy parts of the genome more than once).

S-Cdks are themselves subject to regulation by G1-Cdk (cyclin D1–3 with Cdk4 or Cdk5) and G1/S-Cdk (cyclin E with Cdk2), both of which can stimulate cyclin A synthesis. Two major cancer pathways converge on this checkpoint via the cyclin-Cdks:

- **G1-Cdk** responds positively to mitogenic (progrowth) environmental signals like platelet-derived growth factor (PDGF) or epidermal growth factor (EGF). Activated G1-Cdk phosphorylates and inactivates the retinoblastoma (Rb) protein which releases the transcription factor E2F to stimulate G1/S-Cdk and S-Cdk synthesis that are necessary for progression.
- **G1/S-Cdk and S-Cdk** are also responsive to DNA damage via the p53 pathway. On DNA damage, the transcription factor p53 is phosphorylated and stimulates transcription of the p21 gene. p21 protein is an inhibitor of both G1/S-Cdk and S-Cdk. Both the Rb and p53 are regulators of the restriction-point. Loss of function of either disables aspects of the negative control pathways. Rb and p53 are commonly mutated in cancer and both are therefore considered ‘tumour suppressor genes’ (see p. 46).

G2/M checkpoint

The G2/M checkpoint prevents entry into mitosis in the presence of DNA damage or non-replicated DNA. M-Cdk (cyclin B with Cdk1) accumulates towards the end of G2 but is inactive. Activation of M-Cdk is complex and includes dephosphorylation of M-Cdk by the phosphatase Cdc25. Activated M-Cdk has three roles at the G2/M checkpoint:

- Initiate chromosome condensation
- Promote breakdown of the nuclear membrane
- Initiate assembly of the mitotic spindle.

To achieve this M-Cdk phosphorylates a number of proteins at this checkpoint. The phosphorylation of condensin is probably necessary to coil the DNA and initiate chromosome condensation, phosphorylation of nuclear pore and lamina proteins probably initiates breakdown of the nuclear membrane, and phosphorylation of microtubule-associated proteins and catastrophe factors are both required for assembly of the mitotic spindle. DNA damage and the presence of non-replicated DNA negatively regulate M-Cdk and prevent entry into mitosis. The kinases that phosphorylate p53 in response to DNA damage and block progression through the restriction point can also phosphorylate and inhibit Cdc25, inactivating M-Cdk. Thus DNA damage also blocks cell cycle progression at this checkpoint.

Met/Ana checkpoint

The metaphase to anaphase checkpoint is regulated by protein degradation. The anaphase-promoting complex APC/C, which is activated by Cdc20, is a ubiquitin ligase that transfers a small protein, ubiquitin, to other proteins marking them for degradation. The primary targets are securin, and the S- and M-cyclins of the cyclin-Cdks present at the start of mitosis.

Securin is an inhibitor of a protease called ‘separase’, which, on release, digests the cohesin that holds the two sister chromatids together allowing them to be pulled apart by the mitotic spindle. APC/C activity is tightly controlled but the complete mechanism remains obscure. It includes a negative feedback loop involving M-Cdk which phosphorylates APC/C and increases its affinity for Cdc20. Thus M-Cdk induces its own inactivation by activating the ligase that ensures degradation of its own cyclin. APC/C is also negatively-regulated via an unknown pathway by kinetochores that remain unattached to the mitotic spindle, thus chromatid separation is inhibited until all 46 duplicated chromosomes are on the spindle.

Synthesis and secretion

Protein translation

The mature mRNA is transported through the nuclear pore into the cytoplasm for translation into protein by ribosomes (Fig. 2.12).

- The two subunits of ribosomes (the 40S and 60S) are formed in the nucleolus from multiple proteins and several rRNAs, before transport to the cytoplasm.
- In the cytoplasm, the two subunits interact on an mRNA molecule, usually via ribosome binding sites encoded in the untranslated 5' region of the message. The mRNA is then pulled through the ribosome until a translation initiation codon is encountered (usually an AUG coding for methionine).
- The triplets of adjacent bases of the mRNA (codons) are exposed and recognized by complementary sequences, or anti-codons, in tRNA molecules that dock on the ribosome.
- Each tRNA molecule carries an amino acid specific to the anti-codon. As the mRNA is pulled through the ribosome in the 5' to 3' direction, amino acids are transferred from tRNA molecules and sequentially linked to the carboxy-terminus of the growing polypeptide by the peptidyl transferase activity of the ribosome.
- The poly-A tail of the mRNA is not translated (3' untranslated region) and is preceded by a translational stop codon, UAA, UAG or UGA.

Translation of secreted or integral membrane proteins is different. Typically, the first few amino acids of the amino terminus of the nascent polypeptide exit the ribosome and are recognized by a signal recognition particle (SRP) that stops translation until the complex is docked onto the ER via the SRP receptor. Translation then continues and the protein is translocated into or through the ER membrane via the Sec61 translocation complex as it is being synthesized (co-translational transport).

Protein structure

The amino acid sequence of a polypeptide chain (its **primary structure**) ultimately determines its shape. The weak bonds (hydrogen bonds, electrostatic and van der Waals interactions) formed between the side chains and/or the peptide backbone of the different amino acids provide the **secondary structure** (α -helices, β -strands, loops). These are in turn folded into a three-dimensional, **tertiary structure** to provide functional protein domains of 40–350 amino acids. The modular nature of domains allows their functionality to be combined in protein complexes of different proteins or, by gene fusion and/or exon skipping, into new multidomain single polypeptides. This final level of organization is the **quaternary structure**.

In cells, the folding of polypeptides into fully functional proteins is facilitated by an assortment of molecular chaperones, e.g. heat shock proteins (HSP), which bind to partially folded polypeptides and prevent the formation of inappropriate bonds.

Lipid synthesis

Fatty acids, molecules with a hydrocarbon chain with 4–28 carbons, are central to cellular life and human metabolism. They form the hydrophobic moiety of membrane lipids (see p. 17), they are precursors for short-lived, near acting lipid paracrine factors such as leukotrienes and prostaglandins, and they are energy stores particularly in the form of triglycerides.

Fatty acids as an energy store

Long chain fatty acids can be incorporated into triglycerides, which are relatively inert and lipophilic compounds that can be stored as fat droplets in cells (particularly adipocytes). When blood glucose is low, these triglycerides are hydrolysed, secreted into the bloodstream as free fatty acids, and distributed as an energy source for the cells of the body. In the recipient cell, fatty acids are metabolized in the mitochondrion to produce acetyl-CoA for the Krebs cycle (see p. 31). This is a particularly efficient storage system as gram for gram, triglyceride produces six times the amount of energy than glycogen and occupies less volume in the cell.

Essential fatty acids

Unsaturated fatty acids (UFAs) have carbon–carbon double bonds that are introduced by desaturase enzymes by removal of the hydrogens. The remaining hydrogens on either side of the double bond can be on the same side of the chain (*cis*) or on opposite sides (*trans*). The acyl chain of *cis* UFAs is kinked, which influences the packing of membrane lipids and the function of the membrane barrier. Humans have desaturases that can introduce some double bonds but lack a desaturase required to make linoleic acid or alpha-linolenic acid. These fatty acids have double bonds 6 and 3 carbons from their respective omega ends (the methyl end of the chain). Omega-6 and omega-3 UFAs are essential fatty acids that must be obtained from the diet (see Ch. 5). They are precursors of arachidonic acid and eicosapentaenoic acid, respectively, from which cyclo-oxygenase 1 and 2 (cox-1 and 2) (see p. 826) produce the paracrine factors that play a role in inflammation, pain, fever, and airway constriction.

Intracellular trafficking, exocytosis (secretion) and endocytosis

The molecular composition, the lipids, proteins and cargo of each type of organelle is different and distinct from the plasma membrane, yet there is a continuous flux of material between many of the different compartments. Much of this flow is via vesicles that bud from one compartment to fuse with another. It is regulated by an array of lipids and membrane proteins (coat proteins, adaptors, signalling molecules and fusion proteins).

- **Budding** of vesicles involves recruitment of coat proteins and adaptors to the membrane. Thus, a receptor on binding to its ligand may stimulate a kinase to phosphorylate neighbouring phosphatidylinositol, or activate an associated small GTPase (Arf or Sar1), increasing their affinities for a coat protein or adaptor. The coat protein (clathrin at the plasma membrane, COPI at the Golgi, COPII in the ER) forms a mesh around the developing vesicle (Fig. 2.4). Fully-formed vesicles normally shed their coat (often triggered by GTP hydrolysis by the GTPase), leaving the adaptor/receptor/lipid combination to identify the vesicle.
- **Targeting and trafficking** is mediated by a different family of GTPases (Rab proteins) that recognize the combination of vesicle surface markers and targets them appropriately. Once activated by GTP, the Rab proteins are lipid-anchored to the vesicle where they engage with a diverse pool of Rab effectors. These can be motor proteins that traffic the vesicle along the microfilament and microtubule fibres of the cytoskeleton, or tethering proteins on the target membrane.
- **Fusion** is accomplished by membrane-fusion SNAREs (Fig. 2.4). The v-SNARE protein on the vesicle (often

associated with the Rab effector) interacts with the t-SNARE on the target membrane to facilitate fusion of the two compartments (distinct combinations of v-SNARE and t-SNARE specify particular pathways).

Vesicles that fuse with the plasma membrane replenish membrane lipids and proteins and also release cargo extracellularly (*exocytosis*; Fig. 2.4). Clathrin-coated vesicles are also used to recycle protein from the plasma membrane, and import extracellular cargo to internal compartments called *endosomes*. From endosomes cargo such as receptors is recycled back to the membrane, or cargo is sent for degradation in the lysosome in the process called *endocytosis*.

Pinocytosis and **phagocytosis** (see p. 19) are forms of endocytosis. Endocytosis can also occur via plasma membrane microdomains or lipid rafts called caveolae which pinch in to form uncoated vesicles that fuse with endosomes. Endocytosed vesicles can also be transported across the cell in a process called *transcytosis*. For example, cargo can be endocytosed at the apical surface of an epithelial cell and exocytosed across the basolateral membrane.

Energy production

As food is catabolized, cells temporarily store the energy released in carrier molecules. These include reduced nicotinamide adenine dinucleotide and reduced nicotinamide adenine dinucleotide phosphate (**NADH** and **NADPH**, respectively) that release energy as they are oxidized to NAD^+ and NADP^+ . The molar ratio of NAD^+ to NADH is typically high in a cell because NAD^+ is used as an oxidizing agent in catabolic pathways. In contrast, the molar ratio of NADP^+ to NADPH is typically low because NADPH is used as a reducing agent in anabolic reactions. The most versatile carrier is adenosine triphosphate (**ATP**). ATP can be hydrolysed to ADP and phosphate (Pi) and the release of energy used to power less favourable reactions.

The lipids and polysaccharides provide the most energy in a human diet, although protein can also be used. Enzymes secreted into the gut break down these polymers to their respective building blocks of fatty acids and sugars that are absorbed by the apical membrane of the gut epithelium (the transporters involved in the transcellular transport of glucose across the enterocyte are described in Figure 6.24). Fatty acids and sugars are further catabolized by enzyme pathways inside the cell to produce an array of activated carrier molecules.

Glycolysis

The six-carbon glucose is primarily catabolized in 10 steps by enzymes of the glycolytic pathway (see Fig. 8.25) to produce two three-carbon molecules of the carboxylic acid pyruvate. Glycolysis occurs in the cytosol and the first three steps actually consume energy ($2 \times \text{ATP}$), but the remaining six steps generate $4 \times \text{ATP}$ and $2 \times \text{NADH}$, giving a net return of $2 \times \text{ATP}$ and $2 \times \text{NADH}$.

Pyruvate is central to metabolism. It can be catabolized as fuel for the Krebs cycle and oxidative phosphorylation. It can regulate the cellular redox state by dehydration to lactate and regeneration of NADH. It can be a precursor for anabolism of fuels (glucose, glycogen and fatty acids) or amino acids, via conversion to alanine. The fate of pyruvate depends on the environmental conditions and needs of the cell.

Under anaerobic conditions, e.g. in skeletal muscle following prolonged exercise where NAD^+ must be regenerated

(because it is needed as an oxidizing reagent in the catabolism of glucose), pyruvate is **reduced** to lactate as NADH is **oxidized** to NAD^+ in a '**redox**' reaction catalysed by lactate dehydrogenase. This allows the muscle to continue to catabolize glucose to generate ATP under conditions in which metabolic oxygen is limiting. The lactate is secreted into the bloodstream and is ultimately metabolized by the liver back into glucose by gluconeogenesis consuming $6 \times \text{ATP}$ in the process. This cycle of anaerobic respiration that produces lactate in muscle, which is released into the bloodstream to be taken up by the liver for reversion to glucose is known as the **Cori cycle**.

Krebs cycle

Under aerobic conditions, the fate of pyruvate is different. It is transported into the mitochondrion, where it is decarboxylated to acetyl-CoA and NADH, with CO_2 released as a waste product. The acetyl-CoA formed from pyruvate (or from catabolism of amino acids or β -oxidation of fatty acids) enters the Krebs cycle in the matrix of the mitochondrion, where it is condensed with the 4-carbon oxaloacetate to form the 6-carbon citric acid. Citric acid has three carboxylate groups providing the alternative names for the Krebs cycle (the citric acid or tricarboxylic acid cycle). In eight reactions, the Krebs cycle oxidizes two of the four carbons of citric acid to $2 \times \text{CO}_2$, regenerates oxaloacetate to enter the next cycle, and in the process, provides enough energy to produce $1 \times \text{GTP}$, $3 \times \text{NADH}$ and $1 \times$ reduced flavin adenine dinucleotide (FADH_2 , a carrier of electrons much like NADH). The latter two products feed their electrons into the electron transport chain where they are used to make ATP from ADP and Pi, a process known as oxidative phosphorylation.

In addition to energy production, glycolysis and the Krebs cycle provide precursors for the anabolism of amino acids, cholesterol, fatty acids, nucleotides amino sugars and lipids.

Oxidative phosphorylation

The activated carriers NADH and FADH_2 carry high energy electrons as hydride (a proton H^+ and two electrons), which are donated to complexes of the electron transport chain, in the process regenerating NAD^+ and FAD as oxidizing agents for continued oxidative metabolism. The electrons are passed down the series of inner membrane proteins of the mitochondrion, moving to a lower energy state at each step until they are finally transferred to oxygen to produce water (hence the requirement for molecular oxygen). The energy released by the electrons is used to efflux protons (H^+) into the inter-membrane space, setting up an H^+ electrochemical gradient, which the ATP synthase (or F_0F_1 ATPase), another integral membrane protein, uses to drive the formation of ATP from ADP and Pi. Oxidative phosphorylation produces the bulk of the cellular ATP. A single molecule of glucose is able to produce a net yield of approximately $30 \times \text{ATP}$. Only two of these come from glycolysis directly.

Cellular degradation and death

Cell dynamics

Cell components are continually being formed and degraded, and most of the degradation steps involve ATP-dependent multienzyme complexes. Old cellular proteins are mopped up by a small cofactor molecule called '*ubiquitin*', which interacts with these worn proteins via their exposed

hydrophobic residues. *Ubiquitin* is a small 8.5 kDa regulating protein present universally in all living cells. Cells mark the destruction of a protein by attaching molecules to the protein. This 'ubiquitination' signals the protein to move to lysosomes or proteosomes for destruction. A complex containing more than five ubiquitin molecules is rapidly degraded by a large proteolytic multienzyme array termed '26S proteasome'. Ubiquitin also plays a role in regulation of the receptor tyrosine kinase in the cell cycle and in repair of DNA damage. The failure to remove worn proteins can result in the development of chronic debilitating disorders. For example, Alzheimer's and frontotemporal dementias are associated with the accumulation of ubiquitinated proteins (prion-like proteins), which are resistant to ubiquitin-mediated proteolysis. Similar proteolytic-resistant ubiquitinated proteins give rise to inclusion bodies found in myositis and myopathies. This resistance can be due to point mutation in the target protein itself (e.g. mutant *p53* in cancer; see p. 46) or as a result of an external factor altering the conformation of the normal protein to create a proteolytic-resistant shape, as in the prion protein of variant Creutzfeldt–Jakob disease (vCJD). Other conditions include von Hippel–Lindau syndrome (p. 634) and Liddle's syndrome (p. 653).

Free radicals

A free radical is any atom or molecule which contains one or more unpaired electrons, making it more reactive than the native species. The major free radical species produced in the human body are the hydroxyl radical (OH), the superoxide radical (O_2^-) and nitric oxide (NO).

Free radicals have been implicated in a large number of human diseases. The hydroxyl radical is by far the most reactive species but the others can generate more reactive species as breakdown products. When a free radical reacts with a non-radical, a chain reaction ensues which results in direct tissue damage by membrane lipid peroxidation. Furthermore, hydroxyl radicals can cause genetic mutations by attacking purines and pyrimidines. Superoxide dismutases (SOD) convert superoxide to hydrogen peroxide and are thus part of an inherent protective antioxidant mechanism. Patients with dominant familial forms of amyotrophic lateral sclerosis (motor neurone disease) have mutations in the gene for Cu–Zn SOD-1 catalases. Glutathione peroxidases are enzymes that remove hydrogen peroxide generated by SOD in the cell cytosol and mitochondria.

Free radical scavengers bind reactive oxygen species. Alpha-tocopherol, urate, ascorbate and glutathione remove free radicals by reacting directly and non-catalytically. Severe deficiency of α -tocopherol (vitamin E deficiency) causes neurodegeneration. There is evidence that cardiovascular disease and cancer can be prevented by a diet rich in substances that diminish oxidative damage (p. 211). The principal dietary antioxidants are vitamin E, vitamin C, β -carotene and flavonoids.

Heat shock proteins

The heat shock response is a highly conserved and ancient response to tissue stress (chemical and physical) that is mediated by activation of specific genes leading to the production of specific heat shock proteins (HSPs). The diverse functions of HSPs include the transport of proteins in and out of specific cell organelles, acting as molecular chaperones (the catalysis of protein folding and unfolding) and the degradation of proteins (often by ubiquitination pathways). As well as heat, cytotoxic chemicals and free radicals can trigger HSP expression. The unifying feature, which leads to the

activation of HSPs, is the accumulation of damaged intracellular protein. Tumours have an abnormal thermotolerance, which is the basis for the observation of the enhanced cytotoxic effect of chemotherapeutic agents in hyperthermic subjects. The HSPs are expressed in a wide range of human cancers and have been implicated in tumour cell proliferation, differentiation, invasion, metastasis, cell death and immune response.

Autophagy

Cells continually recycle material. For example, cellular proteins targeted for degradation can be ubiquitinated and degraded by the proteasome (p. 31), and mRNA can be de-tailed and degraded by the exosome or decapping complex. Cells respond to stresses like starvation by degrading much of their cytoplasmic contents in order to recycle components and survive.

Cells achieve this by **autophagy**, during which everything from sugars, lipids, protein aggregates, ribosomal particles and organelles are enclosed in a double membrane (a vesicle forms a cup shape to extend around the material). The new autophagosome then fuses with a lysosome leading to degradation of the contents by acid hydrolysis. Autophagic induction is complex and still not completely understood, but it has roles in tumour growth, elimination of intracellular microorganisms, and elimination of toxic misfolded proteins such as those that give rise to neurodegenerative disorders. Autophagy can suppress apoptotic cell death induced by chemotherapy, while excessive autophagy in response to starvation can lead to autophagic cell death.

Necrotic cell death

In necrotic cell death, external factors (e.g. hypoxia, chemical toxins, injury) damage the cell irreversibly. Necrotic cell death is associated with ischaemia and stroke, cardiac failure, neurodegeneration, pathogen infection and occurs in the centre of tumours deprived of a blood supply. Characteristically, there is an influx of water and ions, after which the cell and its organelles swell and rupture. Lysosomal proteases released into the cytosol cause widespread degradation. There is a rise in cytosolic calcium, increased reactive oxygen species (ROS), intracellular acidification and ATP depletion. Necrosis is regulated and the cellular processes and activated pathways are still being investigated. Necrotic cell lysis induces acute inflammatory responses owing to the release of lysosomal enzymes into the extracellular environment.

Apoptotic cell death

Most terminally-differentiated cells can no longer replicate and eventually die by apoptosis, a type of programmed cell death. Apoptosis occurs through the deliberate activation of cellular pathways, which function to cause cell suicide. In contrast to necrosis, apoptosis is orderly. Cells are destroyed and their remains phagocytosed by adjacent cells and macrophages without inducing inflammation. Apoptosis is essential for many life processes, including tissue maintenance in the adult, tissue formation in embryogenesis, and normal metabolic processes such as autodestruction of the thickened endometrium to cause menstruation in a non-conception cycle. Cells which have accumulated irreparable DNA damage from toxins or ultraviolet radiation also trigger apoptosis via *p53* protein to prevent replication of mutations or progression to cancer. Many chemotherapy and radiotherapy regimens work by triggering apoptotic pathways in the tumour cell.

FURTHER READING

Weiner LM, Lotze MT. Tumor-cell death, autophagy, and immunity. *N Engl J Med* 2012; 366:1156–1158.

Apoptosis has characteristic features:

- Shrinkage of the cell and its nucleus
- Chromatin aggregation into membrane-bound vesicles called apoptotic bodies
- Cell 'blebs' (which are intact membrane vesicles)
- Absence of inflammatory response.

Apoptosis requires proteases called caspases whose action is very tightly regulated. Caspases not only destroy cell organelles, they cleave nuclear lamin causing collapse of the nuclear envelope and activate, through cleavage, nucleases that degrade DNA. Caspase activation can be achieved by:

- signals from outside the cell (the **extrinsic apoptotic pathway** or the **death receptor pathway**) and
- internal signals, such as DNA damage (the **intrinsic apoptotic pathway** or the **mitochondrial pathway**) (Fig. 2.14).

The **extrinsic pathway** is required for tissue remodeling and induction of immune self-tolerance. Cells marked for apoptosis express a member of the tumour necrosis factor (TNF) death receptor family, such as Fas, on their surfaces. Ligand binding (e.g. by Fas ligand expressed on lymphocytes) causes activation of adaptor proteins which produce a cascade of caspase activation. The extrinsic pathway can be amplified by induction of the intrinsic pathway (see below).

The **intrinsic pathway** centres on increased mitochondrial permeability and release of pro-apoptotic proteins like cytochrome C. Cellular stresses such as growth factor withdrawal, p53-dependent cell cycle arrest, DNA damage, and intracellular reactive oxygen species induce expression of pro-apoptotic Bcl-2 proteins, Bax and Bak. These enter the outer mitochondrial membrane forming pores that release cytochrome C which forms a complex (the apoptosome) with other proteins. The apoptosome activates a caspase cascade.

STEM CELLS

Following fertilization, the newly formed fertilized cell (the zygote) and those following the first few divisions are totipotent, meaning that they can differentiate into any cell type in the adult body. At the blastula stage of embryonic development, these cells undergo a primary differentiation event to become either the trophectoderm or the inner cell mass (ICM). The trophectoderm gives rise to the fetal cells of the placenta, while the ICM are pluripotent and give rise to all other cell types of the body (except those of the placenta), and are more commonly called embryonic stem (ES) cells. Stem cells have two properties:

- **Self renewal:** the ability to divide indefinitely without differentiating.
- **Pluri- or toti-potency:** the capability to differentiate, given the appropriate signals, into any cell type (except fetal placental cells).

As they begin to differentiate, their ability to self renew and their potency is reduced but there remain adult progenitor cells (sometimes erroneously referred to as stem cells), that have a limited ability to self renew and can differentiate into multiple related lineages (multipotent, like haematopoietic 'stem cells') or single lineages (unipotent, like muscle satellite cells). The body uses these partially differentiated progenitor cells to continually replace or repair damaged cells and tissues.

Figure 2.14 Extrinsic and intrinsic apoptotic signalling network. The Fas protein and Fas ligand (FasL) are two proteins that interact to activate an apoptotic pathway. Fas and FasL are both members of the TNF (tumour necrosis factor) family – Fas is part of the transmembrane receptor family and FasL is part of the membrane-associated cytokine family. When the homotrimer of FasL binds to Fas, it causes Fas to trimerize and brings together the death domains (DD) on the cytoplasmic tails of the protein. The adaptor protein, FADD (Fas-associating protein with death domain), binds to these activated death domains and they bind to pro-caspase 8 through a set of death effector domains (DED). When pro-caspase 8s are brought together, they transactivate and cleave themselves to release caspase 8, a protease that cleaves protein chains after aspartic acid residues. Caspase 8 then cleaves and activates other caspases, which eventually leads to activation of caspase 3. Caspase 3 cleaves ICAD, the inhibitor of CAD (caspase activated DNase), which frees CAD to enter the nucleus and cleave DNA. Although caspase 3 is the pivotal execution caspase for apoptosis, the processes can be initiated by intrinsic signalling, which always involves mitochondrial release of cytochrome C and activation of caspase 9. The release of cytochrome C and mitochondrial inhibitor of IAPs is mediated via Bcl-2 family proteins (including Bax, Bak) forming pores in the mitochondrial membrane. Interestingly, the extrinsic apoptotic signal is aided and amplified by activation of tBid, which recruits Bcl-2 family members and hence also activates the intrinsic pathway. Apaf1, apoptotic protease activating factor 1; Bid, family member of Bcl-2 protein; IAPs, inhibitor of apoptosis proteins.

Stem cells have great therapeutic potential and can be obtained from blood from the umbilical cord, which contains embryonic-like stem cells (not as primitive as ES cells but can differentiate into many more cell types than adult progenitor cells) or by reprogramming adult cells to regain stem-like properties (induced pluripotent stem cells, iPSC).

Cancer 'stem cells'

Only a very small proportion (<1%) of the individual cells from a cancer can form a cancer in a recipient immunodeficient mouse. These cells equate with the population that exclude the fluorescent drug Hoechst 33348 due to presence

of a primary active (ABC) drug transporter on their cell surface. They have the characteristics of adult progenitor cells. The high relapse rate of many cancers may well be

due to the persistence of these cancer 'stem cells' and new therapies are required to target these in the initial treatment regimen.

HUMAN GENETICS

In 2003, the Human Genome Project was completed, with all 3.2×10^9 base-pairs of DNA sequenced. Over 99% of the DNA sequence is identical between individuals, but still millions of different base-pair variations occur (variants that occur at a frequency $>1\%$ are called polymorphisms; pathological polymorphisms are called mutations; single nucleotide polymorphisms are called SNPs, pronounced 'snips'). In addition, the genome contains segmental, duplication-rich regions, where the number of duplications varies between people. These are called copy number variations or CNVs. These variations underlie most human differences, and confer genetic disease and susceptibility to many common diseases. To understand this variation, the 1000 Genomes Project was undertaken (completion date 2012), involving sequencing of many genomes from people of Asian, west African and European ancestry. This project will document most of the variation between humans.

Genomic DNA encodes approximately 21 000 genes. However, these protein-encoding genes comprise only about 1.5% of the human genome. About 90% of the remaining genome is transcribed to form RNA molecules, which are not translated into protein (non-coding RNA, ncRNA). Some of these RNAs have known regulatory roles, although the role of many is still unknown. The remaining DNA also contains evolutionarily conserved non-coding regions, some with known enhancer functions, moderately repeated elements (transposons) with probable viral origin, and microsatellites consisting of short simple sequence (1–6 nucleotide) repeats. About 10% of the genome is highly repetitive or 'satellite' DNA, consisting of long arrays of tandem repeats. Satellite DNA largely locates to centromeres and telomeres of chromosomes and regions of inert DNA. It forms a major part of heterochromatin. The function of genomic DNA elements is being investigated under the ENCODE (Encyclopedia of DNA Elements) project.

TOOLS FOR HUMAN GENETIC ANALYSIS

The polymerase chain reaction (PCR)

This technique revolutionized genetic research because minute amounts of DNA, e.g. from buccal cell scrapings, blood spots or single embryonic cells, can be amplified over a million times within a few hours. The exact DNA sequence to be amplified needs to be known because the DNA is amplified between two short (generally 17–25 bases) single-stranded DNA fragments ('oligonucleotide primers') that are complementary to the sequences on different strands at each end of the DNA of interest (Fig. 2.15).

Hybridization arrays

A fundamental property of DNA is that when two strands are separated, e.g. by heating, they will always re-associate and stick together again because of their complementary base sequences. Therefore, the presence or position of a particular gene can be identified using a gene 'probe'

consisting of DNA or RNA, with a base sequence that is complementary to that of the sequence of interest. A DNA probe is thus a piece of single-stranded DNA that can locate and bind to its complementary sequence. Hybridization is utilized in array-based platforms, where thousands and thousands of probes can be analysed in one experiment to investigate global gene expression, large-scale genotyping, gene methylation status and/or for chromosomal aberrations, including for small chromosomal deletion/insertion events or copy number changes (Fig. 2.16).

DNA sequencing

A chemical process known as dideoxy-sequencing or Sanger sequencing (after its inventor) allows the identification of the exact nucleotide sequence of a piece of DNA. As in PCR, an oligonucleotide primer is annealed adjacent to the region of interest. This primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension can be prematurely interrupted when a dideoxynucleotide

Figure 2.15 Polymerase chain reaction. The technique is based on thermal cycling and has three basic steps. **(1)** The double-stranded genomic DNA is heat-denatured into single-stranded DNA. **(2)** The sample is cooled to favour annealing of the primers to their target DNA. **(3)** A thermostable DNA polymerase extends the primers over the target DNA. After one cycle there are two copies of double-stranded DNA, after two cycles there are four copies, and so on.

becomes incorporated (because they lack the necessary 3'-hydroxyl group). As the dideoxynucleotides are present at a low concentration, not all the chains in a reaction tube will incorporate a dideoxynucleotide in the same place; so the tubes contain sequences of different lengths but which all terminate with a particular dideoxynucleotide. Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size/length, simply monitoring the fluorescence as the reaction products elute from the capillary will give the gene sequence (Fig. 2.17).

Sequencing technology has developed dramatically in recent years, to the extent that it is now cost-effective and quick to sequence an individual's whole genome in one experiment. This has massive implications in disease gene discovery but also can raise serious ethical considerations. There are a number of different platforms to perform this high-throughput sequencing (or 'Next Generation Sequencing') and new faster and cheaper ones are being developed. For under £2000 (2011 price), it is possible to sequence all the coding genes in an individual's human genome to catalogue all possible disease-associated and non-disease associated variants in every human gene. As well as sequencing genomic DNA, the technology can be used to sequence RNA (termed RNAseq) to assess accurately gene expression

levels in addition to determining all splice variation and allelic-copy number. This can also be used to assess the effect of methylation on gene expression.

Identification of gene function

Following sequencing of the genome, the challenge is to understand the function of the protein coding genes. Most tools rely on the comparison of a cell or animal's phenotype in the presence or absence of the gene in question. Each tool has different merits and faults.

Cell culture

Human cells can be grown in culture flasks in the laboratory and their behaviour (growth rate, morphology, motility, gene expression profile and biochemistry) characterized. A specific gene can then be introduced in a small plasmid (a circle of DNA from which the gene of interest can be expressed) or incorporated into a virus, and the change in cell behaviour assessed to provide an indication of gene function. Alternatively, if the cell line in question already expresses the gene of interest, its expression can be knocked down by RNA interference (RNAi).

RNAi

RNAi takes advantage of the cellular machinery that allows microRNAs encoded by the genome to regulate the expression of many genes at the level of messenger RNA stability and translation (see [Control of gene expression](#), above). This phenomenon has been exploited in the laboratory to study the function of a gene of interest or, on a much larger scale, the function of each gene in the genome. In such an RNAi screen, a small interfering (si) RNA specific for each gene in the genome is introduced into cells grown *in vitro*, in effect knocking down expression of each gene in ~20 000 separate experiments. The phenotype of the cells in each experiment is then monitored to test the effect of loss of gene expression.

Animal models

The effect of a gene at the organismal level can also be tested by mis-expression/over-expression or knock-out of a particular gene in a model animal. Nematode worms (*Caenorhabditis*), fruit flies (*Drosophila*), zebra fish and rodents have all been genetically engineered to identify the function of a gene of interest. Knock-out models of the higher organisms can be particularly helpful for medical research to provide a model of disease for exploration of therapeutic intervention. A current goal is to mutate or knockout every protein-coding

gene in mouse through large-scale mutagenesis programmes. However, it should be noted that the physiology of rodents and humans can differ.

Genetic polymorphisms and linkage studies

Techniques have been developed to identify and quantitate genetic polymorphisms such as single nucleotide polymorphisms (SNPs; p. 34), microsatellites and copy number variants (CNVs). For example, SNPs consist usually of two nucleotides at a particular site and vary between populations and ethnic groups. They must occur in at least 1% of the population to be a SNP. SNPs can be in coding or non-coding regions of the genes or be between genes and thus may not change the amino acid sequence of the protein.

Linkage disequilibrium

Polymorphisms that are closer together are more likely to have alleles that move together in a block than those further apart. This phenomenon is called 'linkage disequilibrium' and enables, e.g. one SNP variant (tag SNP) in this block to act as a marker for the presence of other SNP variants. Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis, which was found to be tightly linked to a marker on chromosome 7.

The International Hapmap Project

As SNPs close together are inherited in blocks (haplotypes), tag SNPs for each haplotype block are typed and can then be correlated with a specific phenotype. An **International Hapmap Project** has been developed. The *Wellcome Trust Case Control Consortium* was set up to analyse thousands of DNA samples from patients with different diseases in which there is thought to be a genetic component. Utilizing the Hapmap data and the use of high density SNP hybridization arrays, genetic risk associated sequence variants have been found in many diseases and traits including diabetes, cancer, hypertension, Crohn's disease, height and metabolism.

The 'lod score'

The likelihood of recombination between the marker under study and the disease allele must be taken into account. This degree of likelihood is known as the 'lod score' (the logarithm of the odds) and is a measure of the statistical significance of the observed co-segregation of the marker and the disease gene, compared with what would be expected by chance alone.

- Positive lod scores make linkage more likely.
- Negative lod scores make linkage less likely.

By convention, a lod score of +3 is taken to be definite evidence of linkage because this indicates 1000:1 odds that the co-segregation of the DNA marker and the disease did not occur by chance alone.

Genome databases

Information arising from human genome sequencing is publicly available, providing biological information on every gene in the human genome. Information on any gene describing its protein product, function, tissue specific expression, disease association and sequence variation/mutation can all be easily obtained by searching and manipulating computer-based databases.

THE BIOLOGY OF CHROMOSOMES

Human chromosomes

The nucleus of each diploid cell contains 6×10^9 bp of DNA in long molecules called *chromosomes* (Fig. 2.11). Chromosomes are massive structures containing one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself.

Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 'homologous' pairs of chromosomes (22 pairs of '*autosomes*' and two '*sex chromosomes*'). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the *SRY* gene – sex determining region, Y chromosome.)

The chromosomes are classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the **centromere**, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a long arm, referred to as the **p arm** and the **q arm**, respectively (Fig. 2.11d).

Chromosomes can be stained when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark **bands** that is diagnostic for each chromosome. Each band is given a number, and gene mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the *CFTR* gene (in which a defect gives rise to cystic fibrosis) maps to 7q21; that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis, so that after conception the number of chromosomes remains the same and is not doubled. In the female, each ovum contains one or other X chromosome but, in the male, the sperm bears either an X or a Y chromosome.

Chromosomes can only be seen easily in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used for chromosomal analysis, e.g. amniotic fluid, placental cells from chorionic villus sampling, bone marrow and skin (Box 2.1).

The X chromosome and inactivation

Although females have two X chromosomes (XX), they do not have two doses of X-linked genes (compared with just one dose for a male XY) because of the phenomenon of X inactivation or *lyonization* (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females is epigenetically silenced through the action of a regulatory ncRNA, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

Telomeres and immortality

The ends of chromosomes, telomeres (Fig. 2.11d), do not contain genes but many repeats of a hexameric sequence

Box 2.1 Indications for chromosomal analysis

Chromosome studies may be indicated in the following circumstances:

Antenatal

- Pregnancies in women over 35 years
- Positive maternal serum screening test for aneuploid pregnancy
- Ultrasound features consistent with an aneuploid fetus
- Severe fetal growth retardation
- Sexing of fetus in X-linked disorders

In the neonate

- Congenital malformations
- Suspicion of trisomy or monosomy
- Ambiguous genitalia

In the adolescent

- Primary amenorrhoea or failure of pubertal development
- Growth retardation

In the adult

- Screening parents of a child with a chromosomal abnormality for further genetic counselling
- Infertility or recurrent miscarriages
- Learning difficulties
- Certain malignant disorders (e.g. leukaemias and Wilms' tumour)

TTAGGG. Replication of linear chromosomes starts at coding sites (origins of replication) within the main body of chromosomes and not at the two extreme ends. The extreme ends are therefore susceptible to single-stranded DNA degradation back to double-stranded DNA. Thus, cellular ageing can be measured as a genetic consequence of multiple rounds of replication, with consequential telomere shortening. This leads to chromosome instability and cell death.

Stem cells have longer telomeres than their terminally differentiated daughters. However, germ cells replicate without shortening of their telomeres. This is because they express an enzyme called telomerase, which protects against telomere shortening by acting as a template primer at the extreme ends of the chromosomes. Most somatic cells (unlike germ and embryonic cells) switch off the activity of telomerase after birth and die as a result of apoptosis. Many cancer cells, however, reactivate telomerase, contributing to their immortality. Conversely, cells from patients with progeria (premature ageing syndrome) have extremely short telomeres. Transient expression of telomerase in various stem and daughter cells is part of their normal biology.

The mitochondrial chromosome

In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the mitochondria in the cytoplasm of the cell also have their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16 500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation producing ATP. They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes. Virtually all mitochondria are inherited from the mother as the sperm head contains no (or very few) mitochondria. Disorders mapped to the mitochondrial chromosome are shown in Figure 2.18 and discussed on page 40.

GENETIC DISORDERS

The spectrum of inherited or congenital genetic disorders can be classified as the chromosomal disorders, including mitochondrial chromosome disorders, the Mendelian and sex-linked single-gene disorders, a variety of non-Mendelian disorders, and the multifactorial and polygenic disorders (Table 2.1 and Box 2.2). All are a result of a mutation in the genetic code. This may be a change of a single base-pair of a gene, resulting in functional change in the product protein (e.g. thalassaemia) or gross rearrangement of the gene within a genome (e.g. chronic myeloid leukaemia). These mutations can be congenital (inherited at birth) or somatic (arising during a person's life).

Chromosomal disorders

Chromosomal abnormalities are much more common than is generally appreciated. Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4–6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes, although autosomal aneuploidy (a differing from the normal diploid number) is usually more severe than the sex-chromosome aneuploidies. Abnormalities may occur in either the number or the structure of the chromosomes.

Abnormal chromosome numbers

If a chromosome or chromatids fail to separate ('non-disjunction') either in meiosis or mitosis, one daughter cell will receive two copies of that chromosome and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis, it can lead to an ovum or sperm having:

- either an extra chromosome, so resulting in a fetus that is 'trisomic' and has three instead of two copies of the chromosome;
- or no chromosome, so the fetus is 'monosomic' and has one instead of two copies of the chromosome.

Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. **Trisomy 21 (Down's syndrome)** is observed with a frequency of 1 in 650 live births, regardless of geography or ethnic background. This should be reduced with widespread screening (p. 43). Full **autosomal monosomies** are extremely rare and very deleterious. **Sex-chromosome trisomies** (e.g. Klinefelter's syndrome, XXY) are relatively common. The **sex-chromosome monosomy** in which the individual has an X chromosome only and no second X or Y chromosome is known as **Turner's syndrome** and is estimated to occur in 1 in 2500 live-born girls.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement: termed a 'mosaic' individual.

Very rarely, the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triploidy and tetraploidy (four sets) result in spontaneous abortion.

Abnormal chromosome structures

As well as abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to

Figure 2.18 Mitochondrial chromosome abnormalities. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in bold. Diseases due to mutations that impair mitochondrial protein synthesis are shown in blue. Diseases due to mutations in protein-coding genes are shown in red.

ECM, encephalomyopathy; FBSN familial bilateral striatal necrosis; LHON, Leber's hereditary optic neuropathy; LS, Leigh's syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged-red fibres; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia and retinitis pigmentosa; PEO progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; SIDS, sudden infant death syndrome.

Table 2.1 Prevalence of genetic disease

Genetic disease		Congenital malformation	
0.5% of all newborns have a chromosomal abnormality		3–5% of all births result in congenital malformations	
7% of all stillborns have a chromosomal abnormality		30–50% of post-neonatal deaths are due to congenital malformations	
20–30% of all infant deaths are due to genetic disorders		18% of paediatric hospital admissions are for children with congenital malformations	
11% of paediatric hospital admissions are for children with genetic disorders			
12% of adult hospital admissions are for genetic causes			
15% of all cancers have an inherited susceptibility			
10% of chronic diseases of the adult population (heart, diabetes, arthritis) have a significant genetic component			
European incidences per 1000 births			
Single-gene disorders:	10	Congenital malformations:	31
Dominant	7.0	Genetically determined	0.6
Recessive	1.66	Multifactorial	30
X-linked	1.33	Non-genetic	~0.4
Chromosomal disorders:	3.5		
Autosomes	1.69		
Sex chromosomes	1.80		
Although individual genetic diseases are rare, regional variation is enormous – the incidence of Down's syndrome varies from 1/1000 to 1/100 worldwide. Single-gene diseases collectively comprise over 15500 recognized genetic disorders. The global prevalence of all single-gene diseases at birth is approximately 10/1000.			

the DNA and gene sequences may give rise to a genetic disease.

- **Deletions** of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and the individual will not be normal with just the one normal copy remaining on the non-deleted homologous chromosome. Many deletion syndromes have been well described. For example, *Prader-Willi syndrome* (p. 198) is the result of cytogenetic events resulting in deletion of part of the long arm of chromosome 15; *Wilms' tumour* is characterized by deletion of part of the short arm of chromosome 11; and microdeletions in the long arm of chromosome 22 give rise to the *DiGeorge's syndrome*.
- **Duplications** occur when a portion of the chromosome is present on the chromosome in two copies, so the

genes in that chromosome portion are present in an extra dose. A form of neuropathy, *Charcot-Marie-Tooth disease* (p. 1105), is due to a small duplication of a region of chromosome 17.

- **Inversions** involve an end-to-end reversal of a segment within a chromosome, e.g. 'abcdefgh' becomes 'abcfedgh', e.g. *haemophilia* (p. 421).
- **Translocations** occur when two chromosome regions join together, when they would not normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see p. 451 and Fig. 9.16). Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories:
 - **Reciprocal translocations** occur when any two non-homologous chromosomes break simultaneously

Box 2.2 Genetic disorders

Mendelian

- Inherited or new mutation
- Mutant allele or pair of mutant alleles at single locus
- Clear pattern of inheritance (autosomal or sex-linked) dominant or recessive
- High risk to relatives

Chromosomal

- Loss, gain or abnormal rearrangement of one or more of 46 chromosomes in diploid cells
- No clear pattern of inheritance
- Low risk to relatives

Multifactorial

- Common
- Interaction between genes and environmental factors
- Low risk to relatives

Mitochondrial

- Due to mutations in mitochondrial genome
- Transmitted through maternal line
- Different pattern of inheritance from Mendelian disorders

Somatic cell

- Mutations in somatic cells
- Somatic event is not inherited
- Often give rise to tumours

and rejoin, swapping ends. In this case, the cell still has 46 chromosomes but two of them are rearranged. Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); but at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation, with physical manifestations.

- **Robertsonian translocations** occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced as no genetic material is lost and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. Clinically relevant is the 14/21 Robertsonian translocation. A woman with this karyotype has a one in eight risk of having a baby with Down's syndrome (a male carrier has a 1 in 50 risk). However, they have a 50% risk of producing a carrier like themselves, hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down's syndrome in their offspring, and should have their chromosomes checked.

Table 2.2 shows some of the syndromes resulting from chromosomal abnormalities.

Table 2.2 Chromosomal abnormalities: examples of a few syndromes

Syndrome	Chromosome karyotype	Incidence and risks	Clinical features	Mortality
Autosomal abnormalities				
Trisomy 21 (Down's syndrome)	47, +21 (95%) Mosaicism Translocation 5%	1:650 (overall) (risk with a 20- to 29-year-old mother 1:1000; >45-year-old mother 1:30)	Flat face, slanting eyes, epicanthic folds, small ears, simian crease, short stubby fingers, hypotonia, variable learning difficulties, congenital heart disease (up to 50%)	High in first year, but many survive to adulthood
Trisomy 13 (Patau's syndrome)	47, +13	1:5000	Low-set ears, cleft lip and palate, polydactyly, micro-ophthalmia, learning difficulties	Rarely survive for more than a few weeks
Trisomy 18 (Edwards' syndrome)	47, +18	1:3000	Low-set ears, micrognathia, rocker-bottom feet, learning difficulties	Rarely survive for more than a few weeks
Sex chromosome abnormalities				
Fragile X syndrome	46, XX, fra (X) 46, XY, fra (X)	1:2000	Most common inherited cause of learning difficulties predominantly in male Macro-orchidism	
Female				
Turner's syndrome	45, XO	1:2500	Infantilism, primary amenorrhoea, short stature, webbed neck, cubitus valgus, normal IQ	
Triple X syndrome	47, XXX	1:1000	No distinctive somatic features, learning difficulties	
Others	48, XXXX 49, XXXXX	Rare	Amenorrhoea, infertility, learning difficulties	
Male				
Klinefelter's syndrome	47, XXY (or XXYY)	1:1000 (more in sons of older mothers)	Decreased crown-pubis:pubis-heel ratio, eunuchoid, testicular atrophy, infertility, gynaecomastia, learning difficulties (20%; related to number of X chromosomes)	
Double Y syndrome	47, XYY	1:800	Tall, fertile, minor mental and psychiatric illness, high incidence in tall criminals	
Others	48, XXXY 49, XXXXY		Learning difficulties, testicular atrophy	

Mitochondrial chromosome disorders

The mitochondrial chromosome (see Fig. 2.18, p. 37) carries its genetic information in a very compact form; e.g. there are no introns in the genes. Therefore, any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide, there is a statistical likelihood that there will be more mutated mitochondria, and at some point, this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus and hearing loss. Many syndromes have been described.

Myopathies include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged red fibres (MERRF) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see p. 1153).

Kearns–Sayre syndrome includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and mental deficiency due to long deletions and rearrangements. *Leber's hereditary optic neuropathy* (LHON) is the commonest cause of blindness in young men, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene.

Multisystem disorders include *Pearson's syndrome* (sideroblastic anaemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside cytotoxicity.

Analysis of chromosome disorders

The cell cycle can be arrested at mitosis with colchicine and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified (Fig. 2.19). This is an automated process with computer scanning software searching for metaphase spreads and then automatic binning of each chromosome to allow easy scoring of chromosome number and banding patterns. Another approach utilizes genome-wide array based platforms

Figure 2.19 Karyotyping. (a) G-banded spread of metaphase chromosomes, showing trisomy 21 (arrowed) Down's syndrome. (b) Whole chromosome painting probes labelled with different fluorochromes or fluorochrome combinations on 24 colour or mFISH analysis is based on a DNA probe kit. Digital image analysis software analyses the colour information and identifies the chromosomal origin of each individual pixel within the image. Inter-chromosomal rearrangements will show up as colour changes within the aberrant chromosome. (Courtesy of D. Lillington, Medical Oncology Unit, St Bartholomew's Hospital.)

(comparative genomic hybridization (CGH) or chromosomal microarray analysis (CMA)) to identify changes in chromosome copy number and can identify very small interstitial deletions and insertions (<1 Mb in size).

Large region specific probes are labelled with fluorescently tagged nucleotides and used to allow rapid identification of metaphase chromosomes. This approach allows easy identification of chromosomal translocations (Fig. 2.20). High-throughput sequencing is another method to identify deletions, insertions and translocation breakpoints.

Gene defects

Mendelian and sex-linked single-gene disorders are the result of mutations in coding sequences and their control elements. These mutations can have various effects on the expression of the gene, as explained below, but all cause a dysfunction of the protein product.

Mutations

Although DNA replication is a very accurate process, occasionally mistakes occur to produce changes or mutations. These changes can also occur owing to other factors such as radiation, ultraviolet light or chemicals. Mutations in gene sequences or in the sequences which regulate gene expression (transcription and translation) may alter the amino acid sequence in the protein encoded by that gene. In some cases, protein function will be maintained; in other cases, it will change or cease, perhaps producing a clinical disorder. Many different types of mutation occur.

Point mutation

This is the simplest type of change and involves the substitution of one nucleotide for another, so changing the codon in a coding sequence, leading to an amino acid substitution (non-synonymous). For example, in sickle cell disease a mutation within the globin gene changes one codon from GAG to GTG, so that instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties. However, substitutions may have no effect on the function or stability of the proteins produced as several codons code for the same amino acid (synonymous).

Figure 2.20 Fluorescence in situ hybridization (FISH). Two-coloured FISH using a red paint for the ABL gene on chromosome 9 and a green paint for the BCR gene on chromosome 22 in the anaphase cell nucleus. Where a translocation has occurred, the two genes become juxtaposed on the Philadelphia chromosome and a hybrid yellow fluorescence can be seen only in the affected cell nucleus on the right. Insertion or deletion

Insertion or deletion of one or more bases is a more serious change, particularly if the inserted or deleted DNA is not a multiple of three bases, as this will cause the following sequence to be out of frame.

Splicing mutations

If the DNA sequences which direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case, the processed mRNA which is translated into protein by the ribosomes may carry intron sequences or miss exons so altering amino acid composition.

Nonsense mutations

A **nonsense mutation** is a point mutation in a sequence of DNA that results in a premature stop codon.

Single-gene disease

Monogenetic disorders involving single genes can be inherited as dominant, recessive or sex-linked characteristics. Although classically divided into autosomal dominant, recessive or X-linked disorders, many syndromes show multiple forms of inheritance pattern. For example in Ehlers–Danlos syndrome, we find autosomal dominant, recessive and X-linked inheritance. In addition, there is a spectrum between autosomal recessive and autosomal dominance in that having just one defective allele gives a mild form of the disease (semi-dominant), while having both alleles with the mutation results in a more severe form of the syndrome. In some cases, such as factor V Leiden disease, the boundary between dominant and recessive forms is very blurred.

Some monogenetic disorders show a racial or geographical prevalence, e.g. thalassaemia (see p. 390) is seen mainly in Greeks, South-east Asians and Italians; *porphyria variegata* in the South African white population; and Tay–Sachs disease (p. 1042) in Ashkenazi Jewish people. Thus, although the prevalence of some single-gene diseases is very low world-wide, it is much higher in specific populations.

Autosomal dominant disorders

Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder (Fig. 2.21a) occurs when one of the two copies has a mutation and the protein produced by the normal form of the gene cannot compensate. In this case, a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele, and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:

- Those disorders which have a great variability in their manifestation. ‘Incomplete penetrance’ may occur if patients have a dominant disorder but it does not manifest itself clinically in them. This gives the appearance of the gene having ‘skipped’ a generation.
- Dominant traits are extremely variable in severity (variable expression) and a mildly affected parent may have a severely affected child.
- New cases in a previously unaffected family may be the result of a new mutation. In this case, the risk of a further affected child is negligible. Most cases of achondroplasia, for example, are due to new mutations.

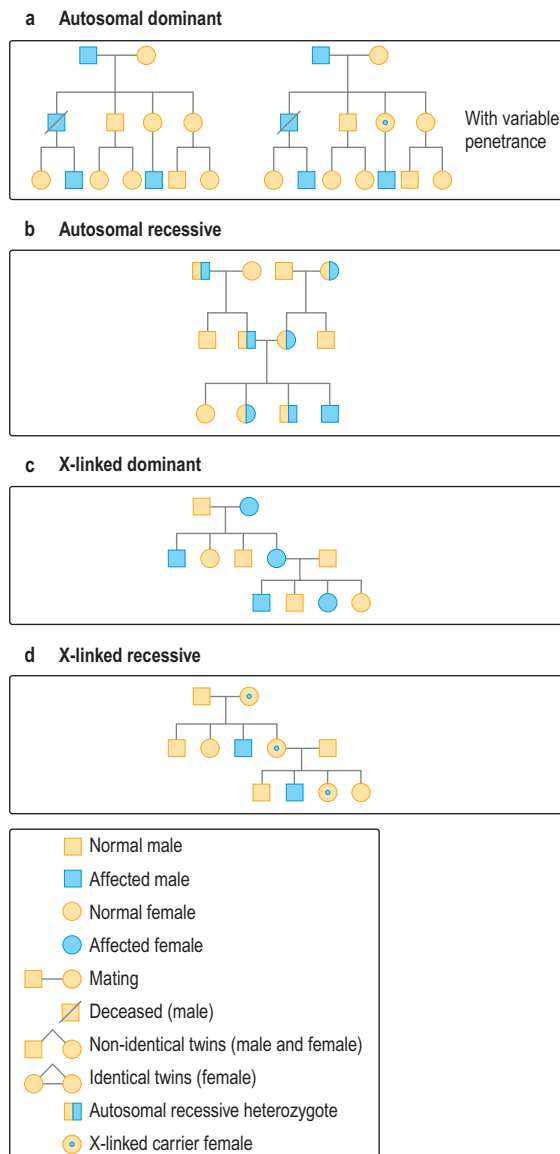

Figure 2.21 Modes of inheritance of simple gene disorders, with a key to the standard pedigree symbols.

Autosomal recessive disorders

These disorders (Fig. 2.21b) manifest themselves only when an individual is homozygous or a compound heterozygote for the disease allele, i.e. both chromosomes carry the same gene mutation (homozygous) or different mutations in the same gene (compound heterozygote). The parents are unaffected carriers (heterozygous for the disease allele). If carriers marry, the offspring have a one in four chance of carrying both mutant copies of the gene and being affected, a one in two chance of being a carrier, and a one in four chance of being genetically normal. Consanguinity increases the risk.

Sex-linked disorders

Genes carried on the X chromosome are said to be ‘X-linked’, and can be dominant or recessive in the same way as autosomal genes (Fig. 2.21c,d).

X-linked dominant disorders

These are rare. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on

SIGNIFICANT WEBSITES

Information on all autosomal single-gene disorders:

<http://www.genetests.org>

<http://www.ncbi.nlm.nih.gov/omim>

their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected man will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

X-linked recessive disorders

These disorders present in males and present only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is haemophilia A (see p. 421), which is caused by a mutation in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one break point being within intron 22 of the factor VIII gene).

Of the offspring from a carrier female and a normal male:

- 50% of the girls will be carriers as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal
- 50% of the boys will have haemophilia as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease as they do not inherit his X chromosome. However, all the female offspring will be carriers as they all inherit his X chromosome.

Other single-gene disorders

These are disorders which may be due to mutations in single genes but which do not manifest as simple monogenic disorders. They can arise from a variety of mechanisms, including the following.

Triplet repeat mutations

In the gene responsible for myotonic dystrophy (p. 1153), the mutated allele was found to have an expanded 3'UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with myotonic dystrophy, people with the late-onset form of the disease had 20–40 copies of the repeat, but their children and grandchildren who presented

with the disease from birth had vast increases in the number of repeats, up to 2000 copies. It is thought that some mechanism during meiosis causes this 'triplet repeat expansion' so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function (Table 2.3). See also page 43 for the phenomenon of 'anticipation'.

Mitochondrial disease

As discussed on pages 37 and 40, various mitochondrial gene mutations can give rise to complex disease syndromes with incomplete penetrance maternal inheritance (Fig. 2.18).

Imprinting

It is known that normal humans need a diploid number of chromosomes of 46. However, the maternal and paternal contributions can be different. Imprinting is relevant to human genetic disease because different phenotypes may result depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long arm of chromosome 15 (15q11-q13) will give rise to the *Prader-Willi syndrome* (PWS), if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to *Angelman's syndrome* (AS) if it is maternally inherited. The affected gene has been identified as ubiquitin (UBE3A).

Complex traits: multifactorial and polygenic inheritance

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes are said to be polygenic. There has been an explosion of genetic discovery about these complex traits with the development of high-throughput genome-wide SNP arrays, which has allowed cost-effective and unbiased screening of large case-control cohorts (in excess of 1000 cases). This has allowed unequivocal identification of SNPs associated with a variety of traits and diseases. For example, over 30 SNPs in immune-related gene loci have been associated with coeliac disease, with over half also associated with other immune-mediated or inflammatory diseases. This indicates that there are many low-risk genetic risk factors associated with complex traits, and common pathways are implicated in different diseases.

Most human diseases, such as heart disease, diabetes and common mental disorders, are multifactorial traits (Table 2.4).

Congenital heart disease	0.5	35
Neural tube defects	0.5	60
Congenital pyloric stenosis	0.3	75
Ankylosing spondylitis	0.2	70
Cleft palate	0.1	76

^aPercentage of the total variation of a trait which can be attributed to genetic factors.

POPULATION GENETICS

The genetic constitution of a population depends on many factors. The *Hardy–Weinberg equilibrium* is a concept, based on a mathematical equation, that describes the outcome of random mating within populations. It states that ‘in the absence of mutation, non-random mating, selection and genetic drift, the genetic constitution of the population remains the same from one generation to the next’.

This genetic principle has clinical significance in terms of the number of abnormal genes in the total gene pool of a population. The Hardy–Weinberg equation states that:

$$p^2 + 2pq + q^2 = 1$$

where p is the frequency of the normal gene in the population, q is the frequency of the abnormal gene, p^2 is the frequency of the normal homozygote, q^2 is the frequency of the affected abnormal homozygote, $2pq$ is the carrier frequency, and $p+q = 1$.

Example: The equation can be used, for example, to find the frequency of heterozygous carriers in cystic fibrosis. The incidence of cystic fibrosis is 1 in 2000 live births. Thus $q^2 = 1/2000$, and therefore $q = 1/44$. Since $p = 1 - q$, then $p = 43/44$. The carrier frequency is represented by $2pq$, which in this case is $1/22$. Thus 1 in 22 individuals in the whole population is a heterozygous carrier for cystic fibrosis.

CLINICAL GENETICS AND GENETIC COUNSELLING

Genetic disorders pose considerable health and economic problems because often there is no effective therapy. In any pregnancy, the risk of a serious developmental abnormality is approximately 1 in 50 pregnancies; approximately 15% of paediatric inpatients have a multifactorial disorder with a predominantly genetic element. 50% of clinical genetics referrals are adults with late-onset disease including neurological, endocrine, gastrointestinal or cancer.

People with a history of a congenital abnormality in a member of their family often seek advice as to why it happened and about the risks of producing further abnormal offspring. Interviews must be conducted with great sensitivity and psychological insight, as parents may feel a sense of guilt and blame themselves for the abnormality in their child.

Genetic counselling should have the following aims:

- **Obtaining a full history.** The pregnancy history, drug and alcohol ingestion during pregnancy and maternal illnesses (e.g. diabetes) should be detailed.
- **Establishing an accurate diagnosis.** Examination of the child may help in diagnosing a genetically abnormal child with characteristic features (e.g. trisomy 21) or whether a genetically normal fetus was damaged *in utero*.
- **Drawing a family tree is essential.** Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity and medical history of family members. Diagnoses may need verification from other hospital reports.
- **Estimating the risk of a future pregnancy being affected or carrying a disorder.** Estimation of risk should be based on the pattern of inheritance. Mendelian disorders (see earlier) carry a high risk; chromosomal abnormalities other than translocations typically carry a low risk. Empirical risks may be obtained from population or family studies.
- **Information giving** on prognosis and management with adequate time given so that all information is discussed openly, freely and repeated as necessary.
- **Continued support and follow-up.** Explanation of the implications for other siblings and family members.
- **Genetic screening.** This includes prenatal diagnosis or preimplantation genetic diagnosis (IVF followed by testing of embryos before implantation) if requested, carrier detection and data storage in genetic registers. A large number of molecular genetic tests are now available
- **The near future?** With the development of cheap high-throughput sequencing, couples could be tested for all genes (termed ‘exome’ sequencing) prior to starting a family to assess if they are carriers of recessive mutations in the same disease-associated gene. This information could then be used in prenatal diagnosis.

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

Genetic anticipation

It has been noted that successive generations of people with, e.g. dystrophin myotonia and Huntington’s chorea, present earlier and with progressively worse symptoms. This ‘anticipation’ is due to unstable mutations occurring within the disease gene. Trinucleotide repeats such as CTG (dystrophin myotonia) and CAG (Huntington’s chorea) expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This type of genetic mutation can occur within the translated region or untranslated (and presumably regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases which have now been shown to be caused by trinucleotide repeat expansion and display phenotypic ‘anticipation’ (Table 2.3).

Prenatal diagnosis for chromosomal disorders

This should be offered to *all* pregnant women. Practice and uptake varies in different maternity units, with some offering screening only to high-risk mothers. The risks of Down’s

SIGNIFICANT WEBSITE

Information on molecular genetic tests:

<http://www.geneclinics.org>

syndrome increase disproportionately and rapidly for children born to mothers older than 35 years. Infants born to mothers with a history or family history of other conditions due to chromosomal abnormalities may be at increased risk.

Personal choice

There should be a detailed discussion with all mothers as to the possible consequences of each screening test before they are offered it. In particular, they should have an understanding of the failure rates, the detection rates, the false positive and the false negative rates of each test so that they can properly exercise choice.

Investigations

The choice of investigation depends on gestational age:

7–11 Weeks (vaginal ultrasound)

Ultrasound is used to confirm viability, fetal number and gestation by crown-rump measurement.

11–13 Weeks and 6 days (combined test)

The combined test comprises:

- Ultrasound for nuchal translucency measurement (normal fold <6 mm) to attempt to detect major chromosomal abnormalities (e.g. trisomies and Turner's syndrome)
- Testing of maternal serum for pregnancy-associated plasma protein-A (PAPP-A from the syncytial trophoblast) and β -human chorionic gonadotrophin for trisomy 21.

All serum marker measurements are corrected for gestational ages, a multiple of the mean (MOM) value for the appropriate week of gestation. If abnormalities are detected, it is necessary to continue to discuss whether further investigation is desired or not. Chorionic villus sampling (CVS) at 11–13 weeks under ultrasound control to sample the placental site, or amniocentesis at 15 weeks to sample amniotic fluid and obtain the fetal cells necessary for cytogenetic testing, are the next options.

The combined test is more accurate than the triple test alone at 16 weeks (see below).

14–20 Weeks (serum triple or quadruple test)

A serum triple or quadruple test is done if the pregnancy is too advanced for the earlier tests or if the combined test was not offered.

The triple test for chromosomal abnormalities consists of testing maternal serum for:

- α -fetoprotein (low)
- unconjugated oestradiol (low)
- human chorionic gonadotrophin (high) for Down's syndrome and for neural tube defects.

The α -fetoprotein is high for neural tube defects.

The **quadruple test** also measures inhibin A – high in Down's syndrome.

14–22 Weeks

Ultrasound detects structural abnormalities (e.g. neural tube defects; the gestation period for detection depends on severity). The best time to detect congenital heart defects is 18–22 weeks.

Reported detection rates for all congenital defects vary, e.g. from 14–61% for hypoplastic ventricle to 97–100% for anencephaly.

In time, some of these tests are likely to be superseded by the salvage of fetal cells from the maternal blood, from

cervical secretions or by retrieving maternal plasma cell free fetal DNA. Other conditions such as myotonic dystrophy and Huntington's chorea may be detected from fetal circulating nucleic acids.

GENOMIC MEDICINE

Gene therapy

Some genetic disorders, such as phenylketonuria or haemophilia, can be managed by diet or replacement therapy, but most have no effective treatment. One approach to manage inherited genetic disease entails placing a normal copy of a gene into the cells of a patient who has a defective copy of the gene; termed gene therapy.

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation will be necessary because of its potential hazards and the ethical issues.

Two major factors are involved in gene therapy:

- The introduction of the functional gene sequence into target cells
- The expression and permanent integration of the transfected gene into the host cell genome.

Cystic fibrosis (see also p. 821)

CFTR, the cystic fibrosis transmembrane regulator, is an unusual ABC transporter in that it does not function as a primary active transporter but as a ligand-gated chloride channel (Fig. 2.22). The common CF mutation is a 3 bp deletion in exon 10 resulting in the removal of a codon specifying phenylalanine (F508del). In this mutation the CFTR protein is misfolded, thereby causing ineffective biosynthesis and consequently disrupting the delivery of the protein to the cell surface. In the mutation G551 D-CFTR, glycine in position 551 is replaced by aspartate; the CFTR channel reaches the cell surface but fails to open. This has introduced a new era of treatment. VX-770, a potentiating agent which can be given orally, has been developed. It increases the fraction of time that the phosphorylated G551 D-CFTR channel is open allowing bicarbonate and chloride flow across the membrane. Early clinical results are encouraging.

Figure 2.22 Model of cystic fibrosis transmembrane regulator (CFTR). This is an integral membrane glycoprotein, consisting of two repeated elements. The cylindrical structures represent six membrane-spanning helices in each half of the molecule. The nucleotide-binding folds (NBFs) are in the cytoplasm. The regulatory (R) domain links the two halves and contains charged individual amino acids and protein kinase phosphorylation sites (black triangles). N and C are the amino and carboxy termini of the protein, respectively. The branched structure on the right half represents potential glycosylation sites.

FURTHER READING

Dietz HC. New therapeutic approaches to Mendelian disorders. *N Engl J Med* 2010; 363(9):852–863.

There are also over 1000 different mutations of the *CFTR* gene with many mapping to the ATP-binding domains.

Two other routes of gene therapy have been tried, either with placing the wild-type *CFTR* cDNA into an adenovirus vector (see Fig. 15.28) to allow infection of human cells or into a plasmid (an engineered circle of DNA) that is then encapsulated into a liposome to allow transfection of human cells. The latter can be conveyed via an aerosol spray to the lung where the liposome fuses with the cell membrane to deliver the *CFTR* cDNA into the cell. However, neither is yet a treatment option. An alternative method is to suppress premature termination codons and thus permit translation to continue; topical nasal gentamicin (an aminoglycoside antibiotic) has been shown to result in the expression of functional *CFTR* channels.

Adenosine deaminase (ADA) deficiency

Successful gene therapy for this rare immunodeficiency disease has entailed introducing a normal human ADA gene into the patient's lymphocytes to reconstitute the function of the cellular and humoral immune system in severe combined immunodeficiency (SCID).

Pharmacogenomics

This is the study of individual SNPs that determine drug behaviour to explain why some patients give variable response to the particular drug. The potential of pharmacogenomic approaches are usually related to single-gene traits that affect drug metabolism, e.g. SNPs in the gene encoding thiopurine-S-methyl-transferase (TPMT), which metabolizes immunosuppressant drugs (e.g. azathioprine). Patient-specific therapies based on their genetic profile will lead to the development of drugs (or drug combinations).

Stem cell therapy

Stem cell therapy has the potential to radically change the treatment of human disease (see p. 33). A number of adult stem cell therapies already exist, particularly bone marrow transplants. It is currently anticipated that technologies derived from stem cell research can be used to treat a wider variety of diseases in which replacement of destroyed specialist tissues is required, such as in Parkinson's disease, spinal cord injuries and muscle damage.

Ethical considerations

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. With diseases for which there is no cure and currently no treatment (e.g. Huntington's chorea), genetic tests can predict accurately which family members will be affected; however, many people would rather not know this information. One very serious outcome of the new genetic information is that disease susceptibility may be predictable, for example in Alzheimer's disease, so the medical insurance companies can decline to give policies for individuals at high risk. Society has not yet decided who should have access to an individual's genetic information and to what extent privacy should be preserved.

THE GENETIC BASIS OF CANCER

Cancers are genetic diseases and involve changes to the normal function of cellular genes. However, multiple genes

interact during oncogenesis and an almost stepwise progression of defects leads from an overproliferation of a particular cell to the breakdown of control mechanisms such as apoptosis (programmed cell death). This would be triggered if a cell were to attempt to survive in an organ other than its tissue of origin. For the vast majority of cancer cases (especially those in older people), the multiple genetic changes which occur are somatic. For some cancers, however (where the cancer normally occurs at an earlier age), a dominant inherited single-gene defect can give rise to an almost Mendelian trend with lifetime risks of nearly 90%.

Autosomal dominant inheritance

The following are examples of cancer syndromes (see Table 9.3, p. 433) that exhibit dominant inheritance:

- **Retinoblastoma** is an eye tumour found in young children. It occurs in both hereditary (40%) and non-hereditary (60%) forms. The 40% of people with the hereditary form have a germline mutation in the *Retinoblastoma* gene (*RB1*) and are also at risk for developing other tumours, particularly osteosarcoma.
- **Breast and ovarian cancer.** Two major genes have been identified – *BRCA1* and *BRCA2*. A strong family history along with germline mutation of these genes accounts for most cases of familial breast cancer and over half of familial ovarian cancers. *BRCA1* and 2 proteins bind to the DNA repair enzyme Rad51 to make it functional in repairing DNA breaks. Mutations in the *BRCA* genes will lead to accumulation of unrepaired mutations in tumour-suppressor genes and crucial oncogenes.
- **Neurofibromatosis.** Inactivation of the *NF1* gene will lead to constitutive activation of ras proteins.
- **Multiple-endocrine-adenomatosis syndromes** (see p. 997). Multiple endocrine neoplasia type 1 is associated with the *MEN1* gene and type 2 (*MEN2*) is associated with mutations in the *RET* proto-oncogene on chromosome 10 and as such are the exception to all the other syndromes which involve tumour suppressor genes.

Autosomal recessive inheritance

Some relatively rare autosomal recessive diseases associated with abnormalities of DNA repair predispose to the development of cancer:

- **Xeroderma pigmentosum.** There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.
- **Ataxia telangiectasia.** Mutation results in an increased sensitivity to ionizing radiation and an increased incidence of lymphoid tumours.
- **Bloom's syndrome and Fanconi's anaemia.** An increased susceptibility to lymphoid malignancy is seen.

Oncogenes

The genes coding for growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes which, when integrated into the host cell, promoted oncogenesis. These were originally termed viral or 'v-oncogenes', and later their normal cellular counterparts, c-oncogenes, were found. Thus, oncogenes encode proteins that are known to participate in the regulation of normal

cellular proliferation e.g. *erb-A* on chromosome 17q11-q12 encodes for the thyroid hormone receptor. See Table 2.5.

Activation of oncogenes

Non-activated oncogenes, which are functioning normally, have been referred to as 'proto-oncogenes'. Their transformation to oncogenes can occur by three routes.

Mutation

Carcinogens such as those found in cigarette smoke, ionizing radiation and ultraviolet light can cause point mutations in genomic DNA encoding tumour suppressor genes or oncogenes.

Chromosomal translocation

If during cell division an error occurs and two chromosomes translocate, so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes. If this happens then the end of one gene is translocated on to the beginning of another gene, giving rise to a 'fusion gene'. Therefore sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene.

An example of such a fusion gene (the Philadelphia chromosome) occurs in *chronic myeloid leukaemia* (CML, see p. 451). Similarly in *Burkitt's lymphoma*, a translocation causes the regulatory segment of the *myc* oncogene to be replaced by a regulatory segment of an unrelated immunoglobulin.

Viral stimulation

When viral RNA is transcribed by reverse transcriptase into viral cDNA and in turn is spliced into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively, the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the *ras* oncogene.

After the initial activation event, other changes occur within the DNA. A striking example of this is amplification of gene sequences, which can affect the *myc* gene, for example. Instead of the normal two copies of a gene, multiple copies of the gene appear either within the chromosomes (these can be seen on stained chromosomes as

homogeneously staining regions) or as extrachromosomal particles (double minutes). *N-myc* sequences are amplified in neuroblastomas, as are *N-myc* or *L-myc* in some lung small-cell carcinomas.

Tumour suppressor genes

These genes restrict undue cell proliferation (in contrast to oncogenes), and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore, mutations in these genes which disable their function, lead to uncontrolled cell growth in cells with active oncogenes. An example is the germline mutations in genes found in non-polyposis colorectal cancer, which are responsible for repairing DNA mismatches (p. 288).

The *RB* gene was the first tumour suppressor gene to be described (p. 433). In the familial variety, the first mutation is inherited and by chance, a second somatic mutation occurs with the formation of a tumour. In the sporadic variety, by chance both mutations occur in both the *RB* genes in a single cell.

Since the finding of *RB*, other tumour suppressor genes have been described, including the gene *p53*. Mutations in *p53* have been found in almost all human tumours, including sporadic colorectal carcinomas, carcinomas of breast and lung, brain tumours, osteosarcomas and leukaemias. The protein encoded by *p53* is a cellular 53 kDa nuclear phosphoprotein that plays a role in DNA repair and synthesis, in the control of the cell cycle and cell differentiation and programmed cell death – apoptosis. *p53* is a DNA-binding protein which activates many gene expression pathways but it is normally only short-lived. In many tumours, mutations that disable *p53* function also prevent its cellular catabolism. Although in some cancers there is a loss of *p53* from both chromosomes, in most cancers (particularly colorectal carcinomas; see Fig. 9.1) such long-lived mutant *p53* alleles can disrupt the normal alleles' protein. As a DNA-binding protein, *p53* is likely to act as a tetramer.

Thus, a mutation in a single copy of the gene can promote tumour formation because a hetero-tetramer of mutated and normal *p53* subunits would still be dysfunctional. *p53* and *RB* are involved in normal regulation of the cell cycle. Other cancer-associated genes are also intimately involved in control of the cell cycle (Fig. 2.13).

Epigenetics and cancer

The term 'epigenetics' is used to explain changes in gene expression that do not involve changes in the underlying DNA sequence. In cancer, epigenetic silencing can 'switch-off' the expression of tumour suppressor genes. Despite not altering the decoding sequence, the effects of epigenetic changes are stable over rounds of cell division, and sometimes between generations. There are two principal molecular epigenetic mechanisms implicated in cancer:

- Modifications to DNA's surface structure, but not its base-pair sequence – DNA methylation resulting in non-recognition of gene transcription DNA-binding domains.
- Modification of chromatin proteins (in particular histones), which will not only support DNA but bind it so tight as to regulate gene expression – at the extreme, such binding can permanently prevent the DNA sequences being exposed to, let alone acted on by, gene transcription (DNA-binding) proteins.

ANATOMY AND PRINCIPLES OF THE IMMUNE SYSTEM

Immunity can be defined as protection from infection, whether it be due to bacteria, viruses, fungi or multicellular parasites. Like other organs involved in human physiology, the immune system is composed of cells and molecules organized into specialized tissues (Fig. 3.1).

The *primary lymphoid organs* are where the cells originate. Cells and molecules of the immune system circulate in the blood; immune responses do not take place there but are at the site of infection (typically the mucosa or skin). They are then propagated and refined in the *secondary lymphoid organs* (e.g. lymph nodes). After resolution of the infection, immunological memory specific for the pathogen resides in cells (lymphocytes) in the spleen and lymph nodes, as well as being widely secreted in a molecular form (antibodies).

Cells involved in immune responses: origin and function

All immune cells have a common source in the pluripotent stem cells generated in the bone marrow (Fig. 3.1). They have diverse functions (Table 3.1). **T lymphocytes** undergo 'education' in the thymus to avoid self-recognition, and populate the peripheral lymphoid tissue, where **B lymphocytes** also reside. Both sets of lymphocytes undergo activation in the peripheral tissue, to become mature effector cells. B lymphocytes may further differentiate into antibody-secreting plasma cells. Lymphoid tissue is frequently found at mucosal surfaces in non-encapsulated patches, termed **mucosa-associated lymphoid tissue** (MALT).

The immune system

Cells and molecules involved in immune responses are classified into innate and adaptive systems:

- **The innate immune system** is inborn and operates throughout life (pp. 51–55)

- **The adaptive immune system** changes in response to the pathogens it encounters (pp. 58–62).

There are also non-immunological barriers that are involved in host protection, and very often it is the lowering of these that allows a pathogen to take a foothold (Table 3.2).

The immune system is immensely powerful, in terms of its ability to inflame, damage and kill, and it has a capacity to recognize a myriad of molecular patterns in the microbial world. However, immune responses are not always beneficial. They can give rise to a range of autoimmune and inflammatory diseases, known as immunopathologies. In addition, the immune system may fail, giving rise to immune deficiency states. These conditions are grouped under the umbrella of clinical immunology.

A major feature of the immune system is the complexity of the surface-bound, intracellular and soluble structures that mediate its functions. In particular, it is necessary to be aware of the CD (clusters of differentiation) classification (Box 3.1) and the functions of cytokines and chemokines.

Cytokines

These are small polypeptides released by a cell in order to change the function of the same or another cell. These chemical messengers are found in many organ systems, but especially the immune system. Cytokines have become markers in the investigation of disease pathogenesis; therapeutic agents in their own right; and the targets of therapeutic agents (see p. 72). The key features of a cytokine are:

- **pleiotropy**: different effects on different cells
- **autocrine function**: modulates the cell secreting it
- **paracrine function**: modulates adjacent cells
- **endocrine effects**: modulates cells and organs at remote sites
- **synergistic activity**: acting in concert with other cytokines to achieve effects greater than the summation of their individual actions.

The main immune cytokines are the **interferons** (IFNs) and the **interleukins** (IL). The IFNs are limited to a few major types (α , β and γ), whereas there are 35 interleukins.

SIGNIFICANT WEBSITE

For cytokine listings and functions of cytokines and chemokines, and related drugs in development: <http://www.copewithcytokines.de/>.

Figure 3.1 Primary and secondary lymphoid tissue. Lymphocytes are generated as precursors in the bone marrow and differentiate into T (thymus) or B (bone marrow) lymphocytes in the primary lymphoid tissue. Once differentiated, 98% of lymphocytes reside in the secondary lymphoid tissue where the adaptive immune response takes place.

Table 3.1 Main cells involved in the immune response: functions and origin				
Category	Cells	Main functions	Origin	Special features
Myeloid	Neutrophils	Immunity to bacteria and fungi	Bone marrow	Major first-line defence against pathogens
	Eosinophils, mast cells and basophils	Immunity to parasites	Bone marrow	Role in allergy
	Monocytes and macrophages	Immunity to bacteria, fungi, parasites	Bone marrow	Specialized phagocytes; cytokine secretion
Lymphoid	Dendritic cells	Antigen presentation to T lymphocytes	Bone marrow	Key role in activating T lymphocytes
	B lymphocytes	Antibody production	Bone marrow	Have specific receptor for antigen (called 'antibody'). Mature into plasma cells that are 'antibody factories'
	T lymphocytes	Orchestrate immune response against bacteria, fungi, parasites and viruses	Precursors come from bone marrow and undergo selection process in the thymus to avoid self-reactivity	Have specific receptor for antigen (called T cell receptor). Two major subsets: CD4 ('helper' and 'regulatory') and CD8 ('cytotoxic')

Chemokines

The defining feature of chemokines is their function as chemotactic molecules, i.e. they attract cells along a gradient of low to high chemical concentration, particularly from the blood into the tissues and tissues into lymphatics. They also have the ability to activate immune cells. All chemokines have

a similar structure relating to the configuration of cysteine residues, which gives rise to four families:

- **CXC**: two cysteines (C) separated by any other amino acid residue (X)
- **CC**: two cysteines next to each other
- **C**: one cysteine

Table 3.2 Non-immunological host defence mechanisms	
Normal barriers	Events that may compromise barrier function
Physical barriers	
Skin and mucous membranes	Trauma, burns, i.v. cannulae
Cough reflex	Suppression, e.g. by opiates, neurological disease
Mucosal function	Ciliary paralysis (e.g. smoking) Increased mucus production (e.g. asthma) Abnormally viscid secretions (e.g. cystic fibrosis) Decreased secretions (e.g. sicca syndrome)
Urine flow	Stasis (e.g. prostatic hypertrophy)
Chemical barriers	Low gastric pH (gastric acid secretion inhibitors)
Resistance to pathogens provided by commensal skin and gut organisms	Changes in flora (e.g. broad-spectrum antibiotics)

Table 3.3 Features of the innate and adaptive immune responses	
Innate	Adaptive
No memory: quality and intensity of response invariant	Memory: response adapts with each exposure
Recognizes limited number of non-varying, generic molecular patterns on, or made by, pathogens	Recognizes vast array of specific antigens ^a on, or made by, pathogens
Pattern recognition mediated by a limited array of receptors	Antigen recognition mediated by a vast array of antigen-specific receptors
Response immediate on first encounter	Response on first encounter takes 1–2 weeks; on second encounter 3–7 days

^aAntigen is a molecular structure (protein, peptide, lipid, carbohydrate) that generates an immune response.

Box 3.1 The CD classification

This is the ultimate way of defining a cell

- Immune cells are distinguished by the surface receptors and proteins that they express in order to mediate their particular range of immunological functions, e.g. cell–cell signalling, cell activation
- The surfaces are covered with such proteins and indicate the cell lineage or differentiation pathway. The discovery of monoclonal antibodies (proteins tailor-made to bind to a specific target) made this feasible
- Surface molecules defining the origin and function of selected groups of cells are known as clusters of differentiation (CD). Over 300 CD numbers exist
- A clinical example is the number of peripheral blood lymphocytes expressing CD4 ('the CD4 count'), which is used to monitor HIV infection (see p. 178)

An updated listing is available at: <http://www.hcdm.org/>

- CX3C:** two cysteines separated by any three amino acids.

Receptors on the surface are denoted by 'R', and are all distinctive G-coupled protein receptors with seven trans-membrane spanning domains.

Anti-inflammatory drugs that block chemokine functions, or drugs that promote cell activation and migration, e.g. into tumours, are being developed.

CELLS AND MOLECULES OF THE INNATE IMMUNE SYSTEM

Innate immunity provides immediate, first-line, host defence. The key features of this system are shown in Table 3.3. It is present at birth and remains operative at comparable intensity into old age. Innate immunity is mediated by a variety of cells and molecules (Table 3.4). Activation of innate immune responses is mediated through interaction between the:

- pathogen side comprising a relatively limited array of molecules (pathogen-associated molecular patterns, PAMPs)
- host side – a limited portfolio of receptors (pattern recognition receptors, PRRs).

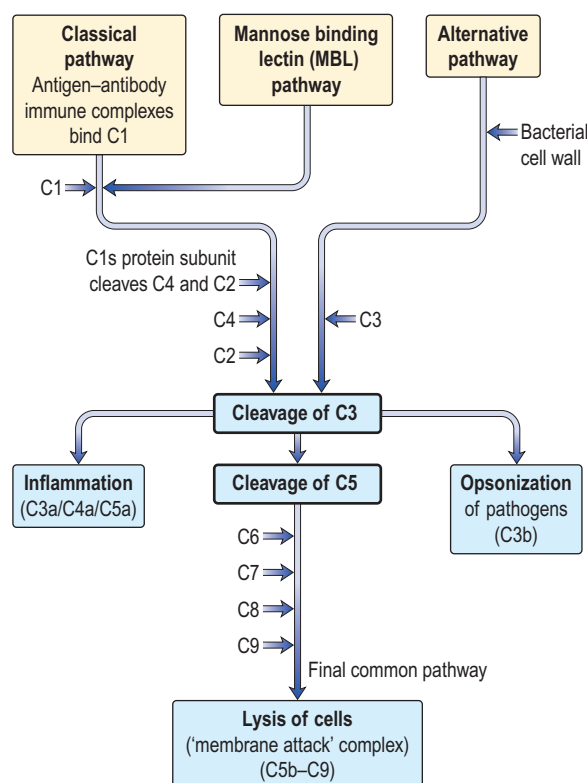

Figure 3.2 The complement pathways and their effector functions.

Activation of certain cells in the innate immune system leads to activation of the *adaptive immune response* (see p. 58).

The *dendritic cell* is especially involved in this process, and forms a bridge between innate and adaptive systems.

Complement

Complement proteins are produced in the liver. Each complement circulates in an inactive form until triggered to become enzymatically active, when it then activates several molecules of the next stage in a series. This *complement cascade* is initiated via three distinct pathways: alternative, classical and mannan-binding lectin (Fig. 3.2). These

Table 3.4 Soluble components of innate immunity

Molecules	Name (examples)	Function	Provide immunity against
Complement	Cascade of >40 proteins	Lyse bacteria; opsonize ^a bacteria; promote inflammation; recruit and activate immune cells	Bacteria, viruses
Collectins	Mannan binding lectin	Binds bacteria; activates complement	Bacteria
Pentraxins	C-reactive protein ^b	Opsonize bacteria	Bacteria
Enzymes	Lysozyme	Present in secretions; cleaves bacterial cell wall	Bacteria

^aOpsonize = coat bacteria to enhance phagocytosis by granulocytes and monocytes/macrophages.

^bC-reactive protein (CRP) is an acute phase protein. Blood level rises 10–100 fold within hours of the start of an infective or inflammatory process, making it extremely useful in monitoring infective or inflammatory diseases, and their response to treatment.

pathways are composed of three distinct enzyme cascades that culminate in the cleavage of C3 and C5. Cleavage of C3 has a number of biological consequences; breakdown of C5 achieves the same and, in addition, provides the triggering stimulus to the final common ('membrane attack') pathway, which provides most of the biological activity (Fig. 3.2).

The main functions of complement activation are to:

- promote inflammation (e.g. through the actions of the anaphylatoxins C3a, C4a and C5a)
- recruit cells (e.g. through chemoattractants)
- kill targeted cells, such as bacteria
- solubilize and remove from the circulation antigen-antibody ('immune') complexes.

During an immune response, removal of immune complexes protects unaffected tissues from the deposition of these large, insoluble composites which could result in unwanted inflammation. Failure of this protective mechanism can result in immunopathology, e.g. in the joints, kidney and eye.

Neutrophils

Neutrophils (see p. 413) phagocytose and kill microorganisms. They are derived from the bone marrow, which can produce between 10^{11} (healthy state) and 10^{12} (during infection) new cells per day. In health, neutrophils are rarely seen in the tissues.

Neutrophil phagocytosis is activated by interaction with bacteria, either directly or after bacteria have been coated (opsonized) to make them more ingestible (Fig. 3.3). The contents of neutrophil granules are released both intracellularly (predominantly azurophilic granules) and extracellularly (specific granules) following fusion with the plasma membrane. Approximately 100 different molecules in neutrophil granules (Table 3.5) kill and digest microorganisms, for example:

- **Myeloperoxidase and cytochrome b_{558}** are key components of major oxygen-dependent bactericidal systems.
- **Cathepsins, proteinase-3 and elastase** are deadly to Gram-positive and Gram-negative organisms, as well as some *Candida* species.
- **Defensins** are naturally occurring cysteine-rich antibacterial and antifungal polypeptides (29–35 amino acids).
- **Collagenase and elastase** break down fibrous structures in the extracellular matrix, facilitating progress of the neutrophil through the tissues.

Granule release is initiated by the products of bacterial cell walls, complement proteins (e.g. inactive complement

Figure 3.3 Opsonization. Bacteria are coated with a variety of soluble factors from the innate immune system (opsonins), which enhance phagocytosis. This leads to engulfment of the bacteria into phagosomes and fusion with granules to release antibacterial agents. iC3b, inactive complement 3b.

3b, iC3b), leukotrienes (LTB_4) and chemokines (e.g. CXCL8, also known as IL-8) and cytokines such as tumour necrosis factor α (TNF- α).

Eosinophils

In contrast to neutrophils, several hundred times more eosinophils are present in the tissues than in the blood, particularly at epithelial surfaces where they survive for several weeks. The main role of eosinophils is protection against

Neutrophil

Neutrophil: phagocytoses bacteria and kills them by releasing antimicrobial compounds (e.g. defensins).

Table 3.5 Contents and function of key neutrophil granules

Function	Primary or azurophilic granules	Secondary or specific granules
Antibacterial	Lysozyme Defensins Myeloperoxidase (MPO) Proteinase-3 Elastase Cathepsins Bactericidal/permeability increasing protein (BPI)	Respiratory burst components (e.g. cytochrome b_{558}) producing reactive oxygen metabolites, such as hydrogen peroxide, hydroxyl radicals and singlet oxygen Lysozyme Lactoferrin
Cell movement		Collagenase CD11b/CD18 (adhesion molecule) N-formyl-methionyl-leucylphenylalanine receptor (FMLP-R)

multicellular parasites such as worms (helminths). This is achieved by the release of pro-inflammatory mediators, which are toxic, cationic proteins. In populations and societies in which such parasites are rare, eosinophils contribute mainly to allergic disease, particularly asthma (see p. 827). Eosinophils have two types of granules:

- **Specific granules** (95%) contain the cationic proteins, of which there are four main types: *major basic protein (MBP)*, *eosinophil cationic protein (ECP)*, *eosinophil neurotoxin*, which are all potently and exquisitely toxic to helminths (ECP also has some bactericidal properties), and *eosinophil peroxidase*, which has similar activity to neutrophil myeloperoxidase.
- **Primary granules** (5%) synthesize and release *leukotrienes C₄ and D₄* and *platelet-activating factor (PAF)* which alter airway smooth muscle and vasculature (see p. 828).

Eosinophils are activated and recruited by a variety of mediators via specific surface receptors, including complement factors and leukotriene (LT) B₄. In addition, the CC chemokines eotaxin-1 (CCL11) and eotaxin-2 (CCL24) are highly selective in eosinophil recruitment. Receptors are also present for the cytokines IL-3 and IL-5, which promote the development and differentiation of eosinophils.

Mast cells and basophils

Mast cells and basophils share features in common, especially in containing:

- histamine-containing granules
- high-affinity receptors for immunoglobulin E (IgE; an antibody type that is involved in allergic disease, see p. 68, 69).

Mast cells are found in tissues (especially skin and mucosae) and basophils in the blood. Both mast cells and basophils release pro-inflammatory mediators which are either pre-formed or synthesized *de novo* (Table 3.6).

Histamine is a low-molecular-weight amine (111 Da) with a blood half-life of less than 5 minutes; it constitutes 10% of the mast cell's weight. When injected into the skin, histamine induces the typical 'weal and flare' or 'triple' response: redness (erythema) due to increased blood flow, swelling (weal) due to increased vascular permeability, and distal vascular changes (flare) due to effects on local axons.

The *complement-derived anaphylatoxins* C3a, C4a and C5a activate basophils and mast cells, as does IgE. The mast cell also has a role in the early response to bacteria through release of TNF- α , in cell recruitment to inflammatory sites such as arthritic joints, in promotion of tumour growth by enhancing neovascularization and in allograft tolerance.

Table 3.6 Mast cell and basophil mediators

Mediators	Effects
Pre-formed:	
Histamine	Vasodilatation Vascular permeability \uparrow Smooth muscle contraction in airways
Proteases	Digestion of basement membrane causes \uparrow vascular permeability and aids migration
Proteoglycans (e.g. heparan)	Anticoagulant activity
Synthesized <i>de novo</i>:	
Platelet-activating factor (PAF) LTB ₄ , LTC ₄ , LTD ₄	Vasodilator Neutrophil and eosinophil activators and chemoattractants Vascular permeability \uparrow Bronchoconstrictors
Prostaglandins (mainly PGD ₂)	Vascular permeability \uparrow Bronchoconstrictors Vasodilators

Monocytes and macrophages

Cells of the monocyte/macrophage lineage are highly sophisticated phagocytes. *Monocytes* are the blood form of a cell that spends a few days in the circulation before entering into the tissues to differentiate into *macrophages*, and possibly some types of dendritic cells.

Blood monocytes

Blood monocytes can be divided into two subsets: those expressing CD14 (a receptor for lipopolysaccharide, a bacterial cell wall component) and those expressing CD14 and CD16 (a receptor for IgG antibodies). *In vitro*, both subsets have the potential to differentiate into myeloid dendritic cells (after culture with IL-4 and granulocyte-monocyte colony stimulating factor, GM-CSF) and into macrophages, which may exist in specialized forms (e.g. alveolar and gut macrophages and osteoclasts).

Tissue macrophages

A key role of tissue macrophages is the maintenance of tissue homeostasis, through clearance of cellular debris, especially following infection or inflammation. They are responsive to a range of pro-inflammatory stimuli, using their pattern recognition receptors (PRR) to recognize pathogen-associated molecular patterns (PAMPs). Once activated, they engulf and kill microorganisms, especially bacteria and fungi. In doing so

Eosinophil

Eosinophil: releases pro-inflammatory mediators to provide immunity against parasites.

Mast cell: releases pro-inflammatory and vasoactive mediators; has a role in allergy.

Macrophage

Monocyte (blood)/macrophage (tissue): ingests and kills bacteria; releases pro-inflammatory molecules; presents antigen to T lymphocytes; necessary in immunity to intracellular pathogens, e.g. mycobacteria.

they release a range of pro-inflammatory cytokines and have the capacity to present fragments of the microorganisms to T lymphocytes (see below) in a process called *antigen presentation*. Recent evidence suggests that evolutionarily conserved molecular patterns in mitochondria (organelles that originally derived from bacteria) can also activate monocytes. These damage-associated molecular patterns (DAMPs) could play a major role in the systemic inflammatory response that follows extensive tissue damage (e.g. following ischaemic injury).

It has been observed that some PAMPs induce the cytoplasmic assembly of large oligomeric structures of PRRs termed *inflammasomes*. There are numerous examples: members of the Nod-like receptor (NLR) family can be activated by stimuli such as viruses, bacterial toxins, and interestingly, crystallized endogenous molecules, including urate. Inflammasomes have potent effects in activating caspases, leading to processing and secretion of pro-inflammatory cytokines such as IL-1 β and IL-18.

Macrophages have pro-inflammatory and microbicidal capabilities similar to those of neutrophils. Under activation conditions, antigen presentation (see p. 57, 58) is enhanced and a range of cytokines secreted, notably TNF- α , IL-1 and IFN- γ . These are necessary for the removal of certain pathogens that live within mononuclear phagocytes (e.g. mycobacteria). Macrophages and related cells may also undergo a process termed *autophagy* (p. 32, Ch. 2). This self-cannibalization is a critical property of many cell types under starvation conditions, but is used by the immune system to destroy intracellular pathogens such as *Mycobacterium tuberculosis*, which otherwise persist within cells and block normal antibacterial processes. Autophagy is also a means of enhancing antigen presentation pathways.

Tissue macrophages involved in chronic inflammatory foci may undergo terminal differentiation into multinucleated giant cells, typically found at the site of the granulomata characteristic of tuberculosis and sarcoidosis (see p. 845).

Dendritic cells

The major function of dendritic cells (DCs) is activation of naive T lymphocytes to initiate adaptive immune responses; they are the only cells capable of this. The definition of a dendritic cell is one that has:

- dendritic morphology (Fig. 3.4)
- machinery for sensing pathogens
- the ability to process and present antigens to CD4 and CD8 T lymphocytes, coupled with the ability to activate these T lymphocytes from a naive state
- the ability to dictate the T lymphocyte's future function and differentiation.

This is a powerful cell type that functions as a critical bridge between the innate and adaptive immune systems.

Types of dendritic cell

The major types are the *myeloid DC (mDC)*, the *plasmacytoid DC (pDC)* and a variety of specialized DCs found in tissues that resemble mDCs (e.g. the Langerhans cell in the skin, see Fig. 24.1). DCs have several distinctive cell surface molecules, some of which have pathogen-sensing activity (e.g. the antigen uptake receptor DEC205 on mDCs) whilst others are involved in interaction with T lymphocytes (Table 3.7). Immature mDCs and pDCs are present in the blood, but at very low levels (<0.5% of lymphocyte/monocyte cells).

Pathogen sensing is a key component of the function of immature DCs, as well as monocytes/macrophages, and is achieved through expression of a limited array of specialized

Figure 3.4 Mature dendritic cell: ingests pathogens; migrates to lymph nodes and presents pathogen-derived antigen to T lymphocytes to enable adaptive immunity.

Table 3.7 Molecules on dendritic cells

	Myeloid DC		Plasmacytoid DC	
	Immature	Mature	Immature	Mature
CD1c	+	++	–	–
CD123 (IL-3 receptor)	–	–	+	++
Molecules involved in co-stimulation of T lymphocytes (CD80, CD86)	+	+++	+	+++
HLA class I and II molecules for antigen presentation to T lymphocytes	+	+++	+	+++

PRR molecules capable of binding to structures common to pathogens, aided by long cell dendrites and pinocytosis (constant ingestion of soluble material).

PRRs include:

- **Mannan-binding lectin**, which initiates complement activity inducing *opsonization* (p. 51, 52).
- **Signalling receptors** such as the PRR known as TLR4 (for toll-like receptor 4), which binds lipopolysaccharide, a molecular pattern found in the cell walls of many Gram-negative bacteria (Table 3.8), whilst others bind double-stranded and single-stranded RNA from viruses. Innate immunity critically depends on toll-like receptor signalling. These receptors act through a critical adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of nuclear factor kappa B (NF- κ B) pathways.
- **Endocytic pattern recognition receptors**, which act by enhancing antigen presentation on macrophages, by recognizing microorganisms with mannose-rich carbohydrates on their surface or by binding to bacterial cell walls and scavenging bacteria from the circulation. All lead to *phagocytosis*.
- **TREM-1** (triggering receptor expressed on myeloid cells) is a cell surface receptor which, when bound to its ligand, triggers secretion of pro-inflammatory cytokines. It is upregulated by bacterial lipopolysaccharides but not in non-infective disorders.

The key principle at play here is that the immune system has devised a means of identifying most types of invading microorganisms by using a limited number of PRRs recognizing common molecular patterns, or PAMPs. This recognition event has been termed a 'danger signal': it alerts the immune

Table 3.8 Toll-like receptors (TLR)

Pattern recognition receptor (PRR)	Pathogen-associated molecular pattern (PAMP)	Pathogen	PRR expressed by
TLR2	Peptidoglycan	Gram-positive bacteria	mDC
TLR3	Double-stranded RNA	Viruses	mDC
TLR4	Lipopolysaccharide	Gram-negative bacteria	mDC
TLR7	Single-stranded RNA	Viruses	pDC
TLR9	Double-stranded DNA	Viruses	pDC

mDC, myeloid dendritic cell; pDC, plasmacytoid dendritic cell.

Figure 3.5 (a) Immature dendritic cells (DCs) in the tissues are activated by pathogens through PAMP–PRR interaction. (b) Multiple rapid changes in gene expression lead to migration to the lymph node as the DC takes on the mature phenotype. During migration there is synthesis of the machinery required for activation of T lymphocytes, shown here in response to signals 1–3.

system to the presence of a pathogen. Sensing danger is a key role of the DC and a key first step towards activation of the adaptive immune system.

DCs and T cell activation

In a sequence of events that spans 1–2 days, immature DCs are activated by PAMPs or DAMPs in the tissues binding to a PRR on DCs. The immature pDC is a small rounded cell that develops dendrites upon activation and secretes enormous quantities of IFN- α , a potent antiviral and pro-inflammatory cytokine. On activation, the DC migrates to the local lymph node with the engulfed pathogen. During migration the DC matures, changing its shape, gene and molecular profile and function within a matter of hours to take on a mature form, with altered functions (Table 3.9, Fig. 3.5), in particular upregulating machinery required to activate T lymphocytes. Once in the lymph node, the mature DC interacts with naive T lymphocytes (antigen presentation), resulting in two key outcomes:

1. Activation of T cells with the ability to recognize peptide fragments (termed epitopes) of the pathogen
2. Polarization of the T cell towards a functional phenotype (see below) that is tailored to the particular pathogen.

The mature DC provides three major signals to naive T cells (Fig. 3.5):

- **Signal 1** = presentation of peptide fragments from the pathogen bound to surface HLA molecules.

Table 3.9 Myeloid dendritic cell (DC) maturation

Immature mDC	Mature mDC
Highly pinocytotic	Ceases pinocytosis
Low level expression of molecules required for T lymphocyte activation	Upregulates CD80, CD86 and HLA molecules
Low level expression of machinery required to process and present microbial antigens	Begins to process microbial antigens (break down into small peptides) in readiness to present them to T lymphocytes (using HLA molecules)
Generally localized and sedentary	Begins active migration to local lymph node
Minimal secretion of cytokines	Active secretion of cytokines in readiness to stimulate T lymphocytes; in particular IL-12

mDC, myeloid dendritic cell.

- **Signal 2** = co-stimulation through CD80 and CD86 interacting with CD28 on T cells.
- **Signal 3** = secretion of cytokines, notably IL-12.

Natural killer (NK) cells

These are described on pages 61, 62.

HLA MOLECULES AND ANTIGEN PRESENTATION

On the short arm of chromosome 6 is a collection of genes termed the major histocompatibility complex (MHC; known as the human leucocyte antigens, or HLA in man), which plays a critical role in immune function. MHC genes code for proteins expressed on the surface of a variety of cell types that are involved in antigen recognition by T lymphocytes. The T lymphocyte receptor for antigen recognizes its ligand as a short antigenic peptide embedded within a physical groove at the extremity of the HLA molecule (Fig. 3.6).

The HLA genes are particularly interesting for clinicians and biologists. First, differences in HLA molecules between individuals are responsible for tissue and organ graft rejection (hence the name 'histo'(tissue)-compatibility). Second, possession of certain HLA genes is linked to susceptibility to particular diseases (Table 3.10).

The human major histocompatibility complex

The human MHC comprises three major classes (I, II and III) of genes involved in the immune response (Fig. 3.7).

HLA classes

Classical class I HLA genes (also termed Ia), are designated *HLA-A*, *HLA-B* and *HLA-C*. Each encodes a class I α chain, which combines with a β chain to form the class I HLA molecule (Fig. 3.6). While there are several types of α chains, there is only one type of β chain, β_2 microglobulin. The HLA class I molecule has the role of presenting short (8–10 amino acids) antigenic peptides to the T cell receptor on the subset of T lymphocytes that bear the co-receptor CD8. As an example of HLA polymorphism, there are nearly 200 allelic forms at the A gene locus. Class I HLA molecules are expressed on all nucleated cells.

Non-classical HLA class I genes are less polymorphic, have a more restricted expression on specialized cell types, and present a restricted type of peptide or none at all. These are the *HLA-E*, *F* and *G* (Ib genes) and MHC class I-related (MIC, or class Ic) genes, *A* and *B*. The products of these genes are predominantly found on epithelial cells, signal

cellular stress and interact with lymphoid cells, especially natural killer cells (see p. 61, 62).

The class II genes have three major subregions, *DP*, *DQ* and *DR*. In these subregions are genes encoding *A* and *B* genes that combine to form dimeric $\alpha\beta$ molecules that present short (12–15 amino acid) peptides to T lymphocytes that bear the CD4 co-receptor. Class II HLA genes (apart from *DRA*) are highly polymorphic. Other genes in this region encode proteins with key roles in antigen presentation (e.g.

Figure 3.6 Structure of HLA class I molecule showing the peptide binding groove that is used to present antigen (Ag) to T lymphocytes.

Table 3.10 HLA associations with immune-mediated and infectious diseases

Disease process	Disease	HLA type
Autoimmunity	Type 1 diabetes	Class II: <i>DQA1*0301/DQB1*0302</i> (susceptibility) <i>DQA1*501/DQB1*201</i> (susceptibility) <i>DQA1*0102/DQB1*0602</i> (protection)
	Multiple sclerosis	Class I: <i>HLA-A24</i> ; <i>HLA-B*18</i> ; <i>HLA-B*39</i>
	Rheumatoid arthritis	<i>DRB1*1501</i> (susceptibility)
	Autoimmune hepatitis	<i>DRB1*0404</i> (susceptibility)
	Goodpasture's syndrome (anti-glomerular basement membrane disease)	<i>DRB1*03</i> and <i>DRB1*04</i> (susceptibility) <i>HLA-DRB1*1501</i> (susceptibility)
	Pemphigus vulgaris	<i>DRB1*0402</i> ; <i>DQB1*0503</i> (susceptibility)
Inflammatory	Celiac disease	<i>DQA1*0501/DQB1*0201</i> (susceptibility)
	Ankylosing spondylitis	<i>HLA-B27</i> (susceptibility)
	Psoriasis	<i>HLA-Cw*0602</i> (susceptibility)
Infectious	Human immunodeficiency virus infection	<i>HA-B27</i> ; <i>HLA-B*51</i> ; <i>HLA-B*57</i> (associated with slow progression of disease)
		<i>HLA-B*35</i> (associated with rapid progression)

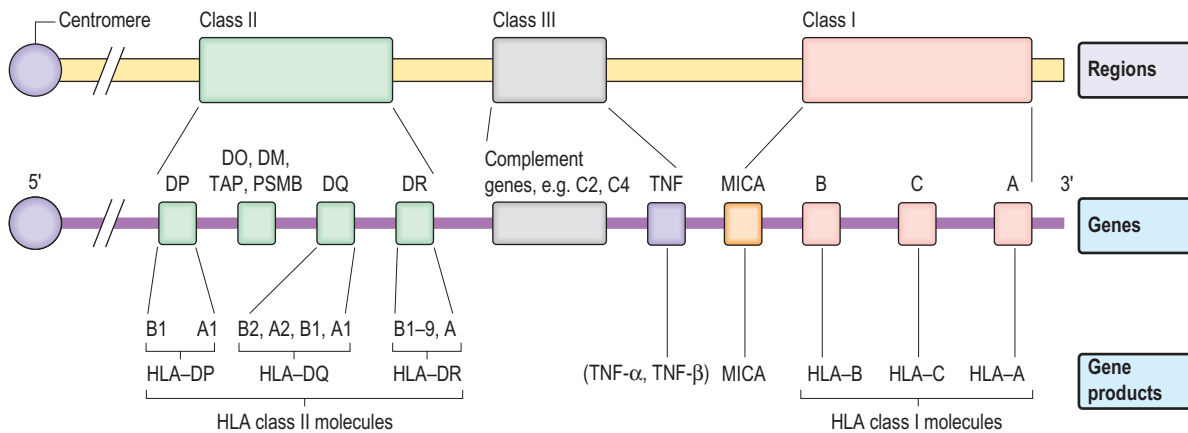

Figure 3.7 The HLA system in man. On chromosome 6 are three major HLA regions (classes I–III) including genes that encode the HLA class I and II molecules, complement genes, the cytokine TNF and other genes involved in antigen presentation (HLA-DO, -DM; transporter associated with processing, TAP; proteasome subunit beta, PSMB; and the non-classical HLA class Ic molecule, MICA).

TAP, HLA-DM, HLA-DO, proteasome subunits; see below). Class II HLA genes are expressed on a restricted cohort of cells that go by the general term of antigen presenting cells (APCs; DCs, monocyte/macrophages, B lymphocytes).

HLA class III genes encode proteins that can regulate/modify immune responses, e.g. tumour necrosis factor (TNF), heat shock protein (HSP) and complement protein (C2, C4).

HLA genotypes and the range of their protein products

HLA genotype is denoted first by the letters that designate the locus (e.g. *HLA-A*, *HLA-DR*, *HLA-DQ*). For class I alleles, this is followed by an asterisk and then a 2- to 4-digit number defining the allelic variant at that locus, often called the HLA type (e.g. *HLA-A*02* is the 02 variant of the *HLA-A* gene). The class II nomenclature is the same, except that both *A* and *B* genes are named (although HLA-DR molecules only require the name of the *B* gene, because the *A* gene is the same in all of us).

Some general principles apply to the HLA genes and their protein products:

- The presence of multiple genes on each chromosome, and the fact that both maternal and paternal genes are co-dominantly expressed, allows considerable breadth in the number of HLA molecules that an individual expresses.
- The existence of polymorphisms at each locus provides great breadth in the number of HLA molecules expressed at a population level. The polymorphic forms of HLA molecules differ predominantly in the peptide-binding groove (Fig. 3.6).

Overall, then, each human can bind a range of peptide epitopes from pathogens to enhance individual protection, and similarly the population has an even greater range of protection, to ensure population survival.

Antigen presentation

HLA molecules bind short peptide fragments which are processed ('chopped up') from larger proteins (antigens) derived from pathogens. The peptide–HLA complex is presented on antigen presenting cells (APCs) for recognition by T cell receptors (TCRs) on T lymphocytes. There are three major routes to antigen processing and presentation:

Figure 3.8 The endogenous route of antigen presentation to CD8 T lymphocytes. Cytosolic proteins derived from self (resting cells) or viruses (virus-infected cells) are broken down by the proteasome (a sort of 'protein recycler') into fragments 2–25 amino acids long. Some of these are taken into the endoplasmic reticulum (ER) by a transporter (TAP), trimmed and loaded into empty HLA class I molecules. These are exported to the surface membrane for presentation to CD8 T lymphocytes.

- **The endogenous route** (Fig. 3.8) is a property of all nucleated cells: the internal milieu is sampled to generate peptide–HLA class I complexes for display ('presentation') on the cell surface. In a healthy cell, the peptides are derived from self-proteins in the cytoplasm (Fig. 3.8) and are ignored by the immune system. In a virus-infected cell, viral proteins are processed and presented. The resulting viral peptide–HLA class I complex is presented to CD8 T lymphocytes that have cytotoxic (killer) function. In an immune response against a virus infection, CD8 T lymphocytes recognizing viral peptide–HLA complexes on the surface of an infected cell will kill it as a means to limit and eradicate infection.

Figure 3.9 The exogenous route of antigen presentation and cross-presentation. External material (e.g. virus particles) is taken into an antigen presenting cell and broken down into specialized compartments by a combination of low pH and proteolysis. Peptides are then loaded into HLA class II molecules for presentation to CD4 T lymphocytes. Material may also be transferred across the cell so that it is loaded onto HLA class I molecules for presentation to CD8 T lymphocytes. This process of cross-presentation is restricted to specialized APCs such as DCs.

Lymphocyte: orchestrates immune responses via cell-to-cell interactions and cytokine release.

- **The exogenous route** (Fig. 3.9) is a property of APCs: the external milieu is sampled. Antigens are internalized, either in the process of phagocytosis of a pathogen, through pinocytosis, or through specialized surface receptors (e.g. for antigen/antibody/complement complexes). The antigen is broken down by a combination of low pH and proteolytic enzymes for 'loading' into HLA class II molecules. At the APC surface the pathogen peptide–HLA class II complex is presented to and able to interact with CD4 T lymphocytes. Presentation by DCs can initiate an adaptive immune response by activating a naive, pathogen-specific CD4 T lymphocyte. Presentation by monocyte/macrophages and B lymphocytes can maintain and enhance this response by activating effector and memory pathogen-specific CD4 T lymphocytes.
- **Cross-presentation** refers to the ability of some APCs (mainly DCs) to internalize exogenous antigens and process them through the endogenous route (Fig. 3.8). This is an essential component in the activation of CD8 cytotoxic T cell responses against a virus.

CELLS AND MOLECULES OF THE ADAPTIVE IMMUNE SYSTEM

The information gained by DCs that interact with a pathogen is passed on, in the form of signals 1–3 (Fig. 3.5b). These activate T lymphocytes in the adaptive immune system, which recognize the same pathogen. T lymphocytes may be involved in pathogen removal directly (e.g. by killing) or

Figure 3.10 Immunoglobulin structure. (a) Basic subunit consisting of two heavy and two light chains. (b) Genes on the Fab and Fc regions of an immunoglobulin. The chain is made up of a V (variable) gene, which is translocated to the J (joining) chain. The VJ segment is then spliced to the C (constant) gene. Heavy chains have an additional D (diversity) segment which forms the VDJ segment that bears the antigen-binding site determinants.

indirectly (e.g. by recruiting B lymphocytes to make specific antibody).

Antigen receptors on T and B lymphocytes

One of the key features of the adaptive immune system is *specificity* for antigen. For example, if you are immunized against the measles virus, you do not have immunity to hepatitis B, and vice-versa. Specificity is conferred by two types of receptor: the TCR on T lymphocytes and an equivalent on B lymphocytes, the BCR. BCRs are also termed surface *immunoglobulin* (slg) and differ from TCRs in also being secreted in large quantities by end-stage B lymphocytes (plasma cells) as soluble immunoglobulins, also known as antibodies.

To maintain protection against the multiplicity of pathogens in our environment, each of us generates great diversity amongst TCRs and antibodies. This is achieved through a mechanism shared by both TCR and antibody, in which distinct families of genes are encoded in the germline, each family (called constant, variable, diversity and joining) contributing a sequence to part of the receptor. Recombination between randomly selected members of each family ensures diversity in the end product. Recombination frequently involves base deletions and additions, adding to the diversity. In the case of antibodies, the result is a potential capacity of $>10^{14}$ different antibody molecules; for TCRs it may be as high as 10^{18} .

Immunoglobulins

In structural terms, antibodies have four chains; two identical heavy and two identical light chains (Fig. 3.10). Each chain contains both highly variable and essentially constant

Table 3.11 Characteristics of the immunoglobulins

	IgG	IgM	IgA	IgE	IgD
	Dominant class of antibody	Produced first in immune response	Found in mucous membrane secretions	Responsible for symptoms of allergy: used in defence against nematode parasites	Found almost solely on B lymphocyte surface membranes
Heavy chain	γ	μ	α	ϵ	δ
Mean adult serum levels (g/L)	IgG (total) = 8–16 G1 = 6.5 G2 = 2.5 G3 = 0.7 G4 = 0.3	0.5–2	IgA (total) = 1.4–4 A1 = 1.5 A2 = 0.2	17–450 ng/mL	0–0.4
Half-life (days)	21	10	6	2	3
Complement fixation					
Classical	++	+++	–	–	–
Alternative	–	–	+	–	–
Binding to mast cells	–	–	–	+	–
Crosses placenta	+	–	–	–	–

regions. The variable parts of the heavy and light chains pair to form the potentially diverse part of the antibody molecule that binds antigen. The constant region of the heavy chain dictates the function of the antibody, and belongs to one of the classes M, G1–4, A1–2, D and E, giving rise to antibodies called IgM, IgG1–4, IgA1–2, IgD and IgE. The characteristics of these different isotypes are shown in Table 3.11.

Antibody production

Essential points about antibody production are:

- IgM is the first isotype to be made in a primary immune response and thus measurement of pathogen specific IgM is a useful diagnostic test for recent infection.
- IgG dominates in the second exposure to antigen.
- IgG and IgM are the most efficient complement activators when bound to antigen in an immune complex.
- IgG antibodies cross the placenta, and can carry both immunity and disease to the unborn fetus.
- IgA antibodies are present in secretions (tears, saliva, GI tract) to give protection to the mucosae.
- As it matures, and under the instruction of T lymphocytes, a B lymphocyte may change the class (class switching), but never the specificity, of the antibody it makes.
- As B lymphocytes mature and are stimulated to undergo further division, minor changes in antibody gene sequence can arise (somatic mutation) potentially allowing antibodies with higher affinity to arise and be selected for the effector response (affinity maturation).

Antibody function

Essential points about antibody function are:

- In host defence, antibodies target, neutralize and remove from the circulation and tissues infectious organisms and toxins, often through recruitment of innate host effector mechanisms such as complement, phagocytes and mast cells (by binding to specific surface receptors on these cells).
- In clinical medicine, specific anti-pathogen antibody levels are used in diagnosing/monitoring infectious

disease, and may also be administered as serum pools to passively provide host protection.

- Antibodies can be raised in animals to generate monoclonal antibodies, which are commonly used in diagnostic immunology tests and increasingly used as therapeutics (e.g. to target cancer cells), often after 'humanization' (see below).

TCR genes and receptor diversity

The genomic organization of TCR genes and principles of generation of receptor diversity are similar to those of immunoglobulin genes. The TCR exists as a heterodimer, with a similar overall structure as the antibody molecule. There are two TCR types:

- α and β chains ($\alpha\beta$ TCR; expressed on all CD4 T lymphocytes and ~90% of CD8 T lymphocytes play a role in adaptive immune responses)
- γ and δ chains ($\gamma\delta$ TCR; fewer in number, mainly on intraepithelial lymphocytes; involved in epithelial defence).

The chains of each type of TCR are divided into variable and constant domains, each domain being encoded by separate gene pools. Like the B lymphocyte producing a single clone of immunoglobulin molecules, the T lymphocyte expresses only one form of TCR once the genes have been rearranged. Unlike antibodies, TCRs do not undergo somatic hypermutation and are not secreted.

T lymphocyte development and activation

T lymphocytes are generated from precursors in the bone marrow, which migrate to the thymus (Fig. 3.11). Only 1% of the cells that enter the thymus will leave it as naive T lymphocytes to populate the lymph nodes. This process (termed thymic selection) leads to a cohort of cells (Table 3.12) with:

- functionally rearranged genes allowing surface expression of a receptor for antigen (the T cell receptor, TCR) alongside the CD3 accessory molecule involved in transducing the antigen-specific signal
- selection of a co-receptor, either CD4 or CD8, to stabilize the interaction between TCR and peptide-HLA:

FURTHER READING

Stone JH, et al. IgG4-related disease. *N Engl J Med* 2012; 366:539–551.

- CD4 T cell responses require presentation of peptide antigens by *self* HLA class II molecules
- CD8 T cell responses require presentation of peptide antigens by *self* HLA class I molecules
- a reduced or absent tendency of the selected TCR to recognize self antigens (thus avoiding autoimmunity).

Thus, during thymic education most TCRs are rejected for further use (negative selection), either because they are unable to bind self HLA molecules, or because they bind with too strong an affinity, which would run the risk of self-reactivity and autoimmune disease. The chosen TCRs (positive selection) have low/intermediate affinity for self HLA molecules. During post-thymic activation of T lymphocytes in the lymph node, TCR interaction with HLA has to be bolstered by additional signals (co-stimulation) provided by DCs. This ensures that T lymphocytes are only activated when the checkpoint of DC maturation has been passed, which will only happen in the presence of pathogens.

Most naive T lymphocytes are resident in the lymph nodes or spleen, whilst 2% are present in the blood, representing a

recirculating pool. Naive T lymphocytes are activated for the first time in the lymph node by antigens presented to their TCRs as short peptides bound to MHC molecules on the surface of DCs (Fig. 3.5). Provision of signals 1–3 (see p. 55) sets off an intracellular cascade of signalling molecule activation, leading to induction of gene transcription in T lymphocytes.

Nuclear factor kappa B (NF- κ B) is a pivotal transcription factor in chronic inflammatory diseases and malignancy. It is found in the cytoplasm bound to an inhibitor I κ B which prevents it from entering the nucleus (see Fig. 2.9). It is released from I κ B on stimulation of the cell and passes into the nucleus, where it binds to promoter regions of target genes involved in inflammation. It is stimulated by, for example, cytokines, protein C activators and viruses. The outcome is T lymphocyte activation, cell division and functional polarization, which is the acquired ability to promote a selected type of adaptive immune response. These processes take several days to achieve. The best described polarities of T cell responses (Table 3.13) are:

- CD4⁺ pro-inflammatory T lymphocytes; T helper 1 (Th1), Th2 and Th17
- CD8⁺ cytotoxic T lymphocytes (CTLs)
- CD4⁺ regulatory responses (Treg).

Through cell division, a proportion of the T lymphocytes that are activated in response to a pathogen undertake these effector or regulatory functions, whilst a proportion is assigned to a memory pool. Once established, effector and memory T lymphocytes have lesser requirements for subsequent activation, which can be mediated by monocytes, macrophages and B lymphocytes.

CD4 T lymphocyte functions

As the pivotal cell in immune responses, the CD4 T lymphocyte influences most aspects of immunity, either through the release of cytokines, or via direct cell–cell interaction, a process often termed ‘licensing’. Licensing critically involves the pairing of CD40 on the APC and CD40 ligand (CD154) on the CD4 T lymphocyte; defects in this process result in antibody deficiency (see below).

Major functions of CD4 T lymphocytes are:

- **Licensing of DCs** during antigen presentation to activate CD8 T lymphocytes and generate cytotoxic cells
- **Licensing of B lymphocytes** to initiate and mature antibody responses, leading to class switching, affinity maturation of antibodies and generation of plasma cells or memory cells
- **Secretion of cytokines** responsible for growth and differentiation of a range of cell types, especially other T lymphocytes, macrophages and eosinophils
- **Regulation of immune reactions.**

Table 3.12 Identification of T lymphocytes

T cell population	Marker	Typical percentages in blood	Additional information
T lymphocytes	T cell receptor CD3	100% of T cells (70% of lymphocytes)	All T cells are thymus-derived
Helper T lymphocytes (Th)	CD4	66% of T cells	Interact with antigen presented by MHC class II molecules
Cytotoxic T lymphocytes (CTL)	CD8	33% of T cells	Interact with antigen presented by MHC class I molecules

Table 3.13 Identification of CD4 T lymphocyte subsets by function

T cell type	Main cytokines causing polarization	Main cytokines produced	Functions	Major role in physiological immune response
T helper 1 (Th1) cells	IL-12	IFN- γ , IL-2, TNF- α	Pro-inflammatory	Organize killing of bacteria, fungi and viruses; activate macrophages to kill intracellular bacteria; instruct cytotoxic T cell responses
T helper 2 (Th2) cells	IL-4	IL-4, IL-5, IL-13	Pro-inflammatory	Organize killing of parasites by recruiting eosinophils; promote antibody responses, especially switching to IgE
T helper 17 (Th17) cells	IL-6, IL-23, TGF- β	IL-17	Pro-inflammatory	Not yet fully defined; capable of recruiting cells and damaging targets; may be more resistant to Treg than Th1/Th2 cells
Regulatory T cells (Treg)	IL-10, TGF- β	IL-10, TGF- β	Regulatory	Regulation of inflammation

T helper 17 cells

The **Th17** subset of T lymphocytes derives its name from the secretion of IL-17. The role of Th17 cells in the immune response is not yet entirely clear. They are capable of secreting numerous pro-inflammatory cytokines (e.g. IL-6, IL-8) and growth factors (GM-CSF). Studies in mice suggest that these cells are critically involved in the protection from pathogens and inflammation associated with the murine versions of diseases such as multiple sclerosis, rheumatoid arthritis and ankylosing spondylitis; it is unknown whether this is also true in man but they do appear to have some role in Crohn's disease. In psoriasis, the full blown disease has been shown to be due to an interaction of Th17 and IL-22.

Regulatory T lymphocytes

The generation of B and T lymphocytes provides a potentially vast array of rearranged antigen receptors. Although there are selection processes to remove lymphocytes with 'dangerous' avidity for 'self' these are not foolproof and the potential for autoreactivity remains. The fact that there is no self-destruction in the vast majority of people implies a state of immunological self tolerance; the controlled inability to respond to self. Several mechanisms operate to maintain this state, including CD4 T lymphocytes that respond to antigenic stimulation by suppressing ongoing immune responses. These regulatory T lymphocytes (Tregs) have different origins, phenotypes and modes of action:

- **CD4⁺ CD25^{hi} Tregs;** express high levels of CD25, the receptor for IL-2; low levels of the IL-7 receptor (CD127); regulate other T lymphocytes by cell-cell contact and also secrete the immune suppressive cytokines IL-10 and TGF- β ; can be generated in the thymus or post-thymically in the periphery; have high expression of the transcription factor Foxp3.
- **Tr1 Tregs;** generated naturally or induced (e.g. by repeated antigen injection); regulate through production of IL-10.

Evidence that Tregs are clinically relevant is given by the example of immune deficiency states in which they are defective. For example, genetic defects in the Foxp3 gene give rise to IPEX (Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked syndrome). Patients with this rare syndrome have defective Tregs and develop a range of conditions soon after birth, including organ-specific autoimmune disease such as type 1 diabetes. Much research effort is directed at harnessing this natural regulatory potential, for

example to control organ graft rejection and autoimmune disease.

CD8 T lymphocyte functions

Cytotoxic CD8 T lymphocytes (CTL) are involved in defence against viruses. CTLs kill virus-infected cells following recognition of viral peptide-HLA class I complexes. CTLs must be activated first in the lymph node by a DC cross-presenting the same viral peptide and licensed by a CD4 T lymphocyte recognizing viral peptide-HLA class II complexes. The same defence mechanism may also apply in tumour surveillance. This is a checkpoint that ensures that CTL responses, which have great destructive power, are only activated against a target for which there is also a CD4 T cell response. CTLs kill via three mechanisms:

- cytotoxic granule proteins (cytolysins such as perforin, granzyme B)
- toxic cytokines (e.g. IFN- γ , TNF- α)
- death-inducing surface molecules (e.g. Fas ligand binds Fas on target cells mediating apoptosis via caspase activation) (see p. 33).

Natural killer (NK) cells

These are bone marrow-derived, present in the blood and lymph nodes and represent 5–10% of lymphoid cells. The name is derived from two features. Unlike B and T lymphocytes, NK cells are able to mediate their effector function *spontaneously* (i.e. killing of target cells through release of perforin, a pore-forming protein) in the absence of previous known sensitization to that target. Also, unlike B and T lymphocytes, NK cells achieve this with a very limited repertoire of germline-encoded receptors that do not undergo somatic recombination. Despite their close resemblance to T and B lymphocytes in morphology, the lack of requirement for sensitization and the absence of gene rearrangement to derive receptors for target cells mean that NK cells are also categorized as a part of the innate immune system. For identification purposes, the main surface molecules associated with NK cells are CD16 (see below) and CD56 (note, NK cells are CD3- and TCR-negative).

The role of NK cells is to kill 'abnormal' host cells, typically cells that are virus-infected, or tumour cells. Killing is achieved in similar ways to CTLs. NK cells also secrete copious amounts of IFN- γ and TNF- α , through which they can mediate cytotoxic effects and activate other components of the innate

KIR, killer cell immunoglobulin-like receptor.

and adaptive immune system. To become activated, NK cells integrate the signal from a potential target cell through a series of receptor-ligand pairings (Table 3.14). These pairings provide activating and inhibitory signals, and it is the overall balance of these that determines the outcome for the NK cell. The balance can be abnormal on a virus-infected or tumour cell, which might have altered expression of HLA molecules, for example, that mark them out for NK cytotoxicity.

In addition, through CD16, which is the low-affinity receptor for IgG (FcγRIIIA), NK cells can kill IgG-coated target cells in a process termed antibody-dependent cellular cytotoxicity (ADCC).

One of the targets of NK cell activating receptors, MICA (non-classical HLA class Ic molecule), is induced under conditions of cellular 'stress', such as might arise during infection or neoplastic transformation. Many viruses have developed immune evasion strategies that avoid presentation of viral proteins to CTLs by interfering with the MHC class I presentation pathway, or circumvent target cell recognition by reducing MICA expression. NK cells detect the reduced levels of MHC class I molecules, which renders infected cells susceptible to killing by NK cells. Likewise, tumours that escape immune surveillance by CTLs through the outgrowth of daughter cells that have low MHC expression also become NK cell targets. That NK cells are vital to antiviral immunity, is indicated by the associations between KIR and susceptibility to chronic infection with viruses, notably the human immunodeficiency virus (see p. 173).

CELL MIGRATION

Immune cells are mobile. They can migrate into the lymph node to participate in an evolving immune response (e.g. a pathogen-loaded DC from the skin, or a recirculating naive T lymphocyte), or can migrate from the lymph node, via the blood, to the site of a specific infection in the tissues. Such migration takes place along blood and lymphatic vessels, and is a highly regulated process.

Taking the example of a DC migrating into the lymph node from the tissues via the lymphatics (Fig. 3.12), this is highly dependent upon expression of the chemokine receptor CCR7 by the migrating cell and of its ligand (secondary lymphoid tissue chemokine, SLC or CCL21) by the target tissue. Likewise, circulating naive lymphocytes are CCR7⁺ and migrate with ease into the lymph nodes from the blood or via tissue recirculation. In addition, naive lymphocytes express L-selectin which binds a glycoprotein cell adhesion molecule (GlyCAM-1) found on the high endothelial venules of lymph nodes. This system can be upregulated in an

Figure 3.12 Migration of an immune cell through a lymph node. (a) T lymphocytes migrate through endothelial venules, which express the chemokine CCL21 (secondary lymphoid tissue chemokine or SLC). (b) Dendritic cells (expressing CCR7), macrophages (expressing CCR2) enter lymph nodes via afferent lymphatics and localize in the paracortex. (c) Antigen presentation (see also Figs 3.8 and 3.9) results in activation of T lymphocytes. (d) Effector T lymphocytes leave lymph node via efferent lymphatic.

inflamed lymph node, leading to an influx of naive lymphocytes and the typical symptom of a swollen node.

Migration into inflamed tissue requires:

- that an affected organ or tissue signals that there is a focus of injury/infection and
- that responding immune cells bind and adhere specifically to that tissue.

This process is highly organized and has a similar basis for all immune cells, involving three basic steps: rolling, adhesion and trans-migration. Each of these is dependent on specialized adhesion molecules, as shown in Figure 3.13.

The controlled regulation of these molecules (e.g. LFA-1 expression) is upregulated on T lymphocytes after activation in the lymph node. ICAM-1 expression on tissue endothelium is sensitive to numerous pro-inflammatory molecules and allows immune cells to be guided from the blood into the tissues. Once there, cells move along a gradient of increasing

Cell migration

The immune system in concert

Figure 3.13 Neutrophil migration. Neutrophils arrive at the site of the inflammation, attracted by various chemoattractants.

(1) **They roll** along the blood vessel wall through interaction between L-selectin, on their surface, binding to a carbohydrate structure (e.g. sialyl-Lewis^x) on the endothelium. E-selectin on the endothelium mediates a similar effect. P-, E- and L-selectin (Platelet, Endothelium and Leucocyte, respectively) are named after the predominant cell type that expresses them and bind to carbohydrate moieties such as sialyl-Lewis^x (CD15s) on immune cells, inducing them to slow and roll along the vessel lumen.

(2) **Firm adhesion** is then mediated via interaction between integrins on the neutrophil and intercellular and vascular cell adhesion molecules (ICAM-I and VCAM-1) on the endothelium. The best known integrin is the heterodimer of CD11a/CD18 (leucocyte function associated antigen-1 – LFA-1) which binds ICAM-1.

(3) **Trans-migration** (diapedesis) then occurs: this is a complex process that involves platelet-endothelial cell adhesion molecule-1 (PECAM-1) and junctional adhesion molecules (JAMS). Following transmigration (diapedesis), mediators such as interleukin-8, macrophage-chemotactic factor and TNF- α attract and activate the neutrophil to the infected tissue where it phagocytoses and destroys the C3b-coated bacteria. PAF, platelet-activating factor; LTB₄, leukotriene B₄.

concentration of mediators such as chemokines in the process of chemotaxis.

THE IMMUNE SYSTEM IN CONCERT

Acute inflammation: events and symptoms

This is the early and rapid host response to tissue injury. Taking a bacterial infection as the classic example:

- Local expansion of pathogen numbers leads to direct activation of complement in the tissues, with ensuing degranulation of mast cells.
- Inflammatory mediators (from mast cells and complement) change the blood flow and attract and activate granulocytes.
- Concomitantly, there are the local symptoms of heat, pain, swelling and redness, and perhaps more systemic symptoms such as fever due to the effect of circulating cytokines (IL-1, IL-6, TNF- α) on the hypothalamus. Indeed, gene mutations that lead to excessive actions of IL-1 (e.g. mutation of the *IL1RN* gene, which encodes a natural IL-1 antagonist) give rise to rare diseases with just these symptoms, as well as bone erosion and skin rashes, that are treatable with IL-1 blockade using soluble IL-1 receptor antagonist (anakinra) or monoclonal anti-IL-1 β antibody.
- Systemically active mediators (especially IL-6) also initiate the production of C-reactive protein (CRP) in the liver.
- Bacterial lysis follows through the actions of complement and neutrophils, leading to formation of fluid in the tissue space containing dead and dying bacteria and host granulocytes ('pus').
- At the site of pathogen entry there is often relative tissue hypoxia. The low oxygen tension has the effect of amplifying the responses of innate immune cells and suppressing the response of adaptive immune cell. This is probably an effective means of preventing excessive

immune activation, which can result in collateral damage (Fig. 3.14).

- The inflammation may become organized and walled off through local fibrin deposition to protect the host.
- Antigens from the pathogen travel via the lymphatics (which may become visible as red tracks in the superficial tissues – lymphangitis) in soluble form or are carried by dendritic cells to establish an adaptive immune response which, at the first host-pathogen encounter, takes approximately 7–14 days.
- The adaptive immune response leads to activation of pathogen-specific T lymphocytes, B lymphocytes and production of pathogen-specific antibody, initially of the IgM class and of low-moderate affinity and subsequently of the IgG class (or IgA if the infection is mucosal) and of high affinity.
- Resolution of the infection is aided by the scavenging activity of tissue macrophages.

Chronic inflammation: events and symptoms

Inflammation arising in response to immunological insults that cannot be resolved in days/weeks gives rise to chronic inflammation. Examples include infectious agents (chronic viral infections such as hepatitis B and C or intracellular bacteria such as mycobacteria) and environmental toxins such as asbestos and silicon. At the intracellular level, key processes of inflammasome generation and autophagy serve to enhance the chronic inflammatory process. Chronic inflammation is also a hallmark of some forms of allergic disease, autoimmune disease and organ graft rejection.

The common feature of these pathological processes is that the inciting stimulus is not easy to remove. For example, some viruses and mycobacteria remain hidden intracellularly; antigens that incite allergy (allergens) may be constantly present in the host's environment; self or donated organs are a resident source of antigens. In many ways, the pathology that results is thus inadvertent; the immune system is caught between the repercussions of not dealing with the infection/insult, and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.

FURTHER READING

Eltzschig HK, Carmeliet P. Hypoxia and inflammation. *N Engl J Med* 2011; 364(7):656–665.

Figure 3.14 Hypoxia and inflammation. At the site of pathogen invasion and necrosis, the oxygen tension is low. Hypoxia acts upon the inflammatory process by amplifying innate immune cell responses and dampening down the adaptive response. Overall, this benefits the host by avoiding an excessive uncontrolled immune response.

Chronic inflammation may lead to permanent organ damage or impaired vascular function and can be fatal. If the inciting stimulus is removed, inflammation resolves. However, inflammation returns rapidly (24–48 hours) on re-exposure. This rapid recall response is the basis for patch testing to identify the cause of contact dermatitis, another form of chronic inflammation, and also for the Mantoux test of tuberculosis immunity.

The main immunological event is the presence of a pro-inflammatory focus comprising T and B lymphocytes and APCs, especially macrophages. If antigen persists, inflammation becomes chronic and the macrophages in the lesion fuse to form giant cells and epithelioid cells. Both Th1 and Th2 reactivity is recognized, but specific syndromes may be polarized towards one or the other (e.g. chronic mycobacterial or viral infection engenders Th1 responses, chronic allergic inflammation Th2).

When the inflammation is sufficiently chronic it may take on the appearance of organized lymphoid tissue resembling a lymph node germinal centre (e.g. in the joints in rheumatoid arthritis, p. 517). There is massive cytokine production by T lymphocytes and APCs, which contributes to local tissue damage. Granulomata, which ‘wall off’ the inciting stimulus, may also arise and result in fibrosis and calcification. Symptoms typically relate to the site of the inflammation and the type of pathology, but there may also be systemic effects such as fever and weight loss.

Crohn’s disease Chronic inflammation is a hallmark of several immune-mediated and autoimmune diseases, but it is often unclear what kick-starts or maintains the inflammatory process. Large scale studies that identify the genetic basis for these disorders (genome-wide association studies, GWAS) are beginning to provide some clues. A good example is Crohn’s disease (CD). Several of the polymorphisms associated with CD reside in genes known to be involved in

inflammasome induction, such as *NOD2*. Cytokine regulation has also emerged as a critical disease pathway in GWAS studies on CD: most notably the *IL-23R* (IL-23 receptor gene), which influences Th17 cell differentiation. Clues like these point to patients with CD having impaired ability to control or terminate inflammasome activity, as well as a predisposition to make polarized pro-inflammatory cytokine responses. This information can now be exploited to devise novel therapeutic approaches.

LABORATORY INVESTIGATIONS OF THE IMMUNE SYSTEM

In the clinical immunology laboratory, proteins and cells can be measured to ascertain the status of the immune system. The results may indicate an undiagnosed inflammatory or infectious disease (e.g. through high C-reactive protein level); a state of immune deficiency (e.g. low concentration of IgG); or a state of immune pathology (e.g. the presence of auto-antibodies or allergen-specific IgE).

Examples of the commoner tests and their interpretation are shown in Table 3.15.

CLINICAL IMMUNODEFICIENCY

Secondary (acquired) versus primary immunodeficiency

Most forms of immunodeficiency are secondary to infection (mainly HIV) or therapy (e.g. corticosteroids, anti-TNF- α monoclonal antibody therapy, cytotoxic anticancer drugs, bone

Table 3.15 Examining the immune system in the clinical immunology laboratory

	Measurement	Interpretation
Proteins	C-reactive protein Immunoglobulins	Raised levels indicate infection or inflammation Low levels indicate antibody deficiency, usually a result of underlying disease or primary immunodeficiency. High levels, e.g. ↑ IgM seen in acute viral infection (hepatitis A)
	Complement C3 and C4	Low levels indicate consumption of complement in immune complex disease
	IgE	Raised levels in allergy; allergen-specific IgE useful to pinpoint the inciting stimulus (e.g. pollen, grass)
Cells	Neutrophils	High levels in bacterial infection; low levels in secondary immune deficiency
	Eosinophils	High levels in allergic or parasitic disease
	CD4 T lymphocytes	Low levels in HIV infection
Function	Neutrophil respiratory burst	Absent in the immune deficiency chronic granulomatous disease
	T lymphocyte proliferation	Abnormally low in primary T cell immune deficiency disease
Autoantibodies (see also Table 11.3 and Box 11.16)	Rheumatoid factor, anti-cyclic citrullinated peptide antibodies (ACPA)	Rheumatoid arthritis
	Double-stranded DNA autoantibodies	Systemic lupus erythematosus
	Acetylcholine receptor antibodies	Myasthenia gravis
	Anti-neutrophil cytoplasmic antibodies (ANCA)	Vasculitis
	Mitochondrial	Primary biliary cirrhosis

marrow ablation pre-transplant). Examples of other secondary immunodeficiencies are:

- **Acquired neutropenias**, which are common (e.g. due to myelosuppression by disease or drugs or the increased rate of destruction in hypersplenism or autoimmune neutropenia) and carry a high risk of infection once the neutrophil count falls below $0.5 \times 10^9/L$.
- **Acquired reductions in levels of immunoglobulins** (hypogammaglobulinaemia), which are seen in patients with myeloma and chronic lymphocytic leukaemia or lymphoma.
- **Impairment of defence against capsulated bacteria**, especially pneumococcus, following splenectomy; such patients should receive pneumococcal, meningococcal and Hib vaccinations as a matter of course (see p. 406).

Primary immunodeficiency is rare and arises at birth as the congenital effect of a developmental defect or as a result of genetic abnormalities (Table 3.16). Gene defects may not become manifest until later in infancy or childhood, and some forms of immunodeficiency typically present in adolescence or adulthood.

Clinical features of immunodeficiency

The infections associated with immunodeficiency have several typical features:

- They are often chronic, severe or recurrent
- They resolve only partially with antibiotic therapy or return soon after cessation of therapy
- The organisms involved are often unusual ('opportunistic' or 'atypical').

The pattern of infection, in terms of the type of organism involved, is indicative (Table 3.17):

- **'Opportunistic' organisms** are of low virulence but become invasive in immunodeficient states, e.g. atypical mycobacteria, *Pneumocystis jiroveci*, *Staphylococcus epidermidis*.

Table 3.16 Classification of immunodeficiencies and the main diseases in each category: apart from AIDS, all diseases shown here are primary immunodeficiencies

Immune component	Examples of diseases
T lymphocyte deficiency	DiGeorge's syndrome Acquired immunodeficiency syndrome/HIV infection T cell activation defects (e.g. CD3γ chain mutation) X-linked hyper-IgM syndrome (XHIM; CD40L deficiency)
B lymphocyte deficiency	X-linked agammaglobulinaemia (XLA) Common variable immunodeficiency (CVID) Selective IgA deficiency (IgAD)
Combined T and B cell defects	Severe combined immunodeficiency (SCID) (e.g. due to defects in common γ chain receptor for IL-2, -4, -7, -9, -15)
T cell-APC interactions	IFN-γ receptor deficiency IL-12 and IL-12 receptor deficiency
Neutrophil defects	Chronic granulomatous disease (CGD) Leucocyte adhesion deficiency (LAD)
Deficiency of complement components	Classical pathway Alternative pathway Common pathway Regulatory proteins Mannan binding lectin

- **Phagocyte defects** cause, e.g. deep skin infections, abscesses, osteomyelitis.
- **Defective antibody** producers experience infections with pyogenic ('pus-forming') bacteria.
- **T lymphocyte deficiency** causes infection with fungi, protozoa and intracellular microorganisms.

Table 3.17 Immune defects and associated infections

Neutropenia and defective neutrophil function
<i>Staphylococcus aureus</i> <i>Staphylococcus epidermidis</i> <i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Proteus mirabilis</i> <i>Pseudomonas aeruginosa</i> <i>Serratia marcescens</i> <i>Bacteroides</i> spp. <i>Aspergillus fumigatus</i> <i>Candida</i> spp. (systemic)
Opsonin defects (antibody/complement deficiency)
<i>Pneumococcus</i> <i>Haemophilus influenzae</i> <i>Meningococcus</i> <i>Streptococcus</i> spp. (capsulated)
Antibody deficiency only
<i>Campylobacter</i> spp. <i>Mycoplasma</i> spp. <i>Ureaplasma</i> spp. Echovirus
Complement lytic pathway defects (C5–9)
<i>Meningococcus</i> <i>Gonococcus</i> (disseminated)
Defect in T cell or T cell–APC responses
<i>Listeria monocytogenes</i> <i>Legionella pneumophila</i> <i>Salmonella</i> spp. (non-Typhi) <i>Nocardia asteroides</i> <i>Mycobacterium tuberculosis</i> Atypical mycobacteria, especially <i>M. avium-intracellulare</i> <i>Candida</i> spp. (mucocutaneous) <i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Pneumocystis jiroveci</i> <i>Toxoplasma gondii</i> Herpes simplex Herpes zoster Cytomegalovirus Epstein–Barr virus

- **Congenital deficiencies** of antibody production are not revealed for several months after birth, due to the 28-day half-life of maternal IgG.

The family history may reveal unexplained sibling death; only females of the family affected; or consanguinity, each of which make a primary genetic syndrome more likely. Graft-versus-host disease (GVHD) may arise as a complication of primary or secondary T lymphocyte immunodeficiency. For GVHD to arise, there must be impaired T lymphocyte function in the recipient and the transfer of immunocompetent T lymphocytes from an HLA non-identical donor (see below). GVHD usually arises from therapeutic interventions such as transfusions or transplantation.

Primary immunodeficiency

T lymphocyte deficiency

DiGeorge's syndrome

This is due to T lymphocyte deficiency. The third and fourth pharyngeal arches, which normally give rise to the parathyroid glands, aortic arch and the thymus, fail to develop. DiGeorge arises in 1–5 per 100 000 of the population and presents at birth with dysmorphic facies, hypoparathyroidism and cardiac defects, followed by infections (fungi, protozoa) in later months. The lack of a location for T lymphocyte development, i.e. the thymus, means that affected children

have reduced/absent T lymphocyte number and proliferation responses. Apart from calcium supplementation, correction of cardiac abnormalities and prophylactic antibiotics, cure has been reported with thymic transplantation using fetal tissue or stem cell transplant (SCT) from HLA identical siblings.

Other T lymphocyte deficiencies

Other T lymphocyte deficiencies caused by single gene defects have been characterized and typically present from the age of 3 months with candidal infections of the mouth and skin, protracted diarrhoea, fever and failure to thrive. Examples include deficiency of CD3 itself; defects in signal transduction pathways; and deficiency of IL-2. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immune deficiencies.

T and B lymphocyte deficiency

Severe combined immunodeficiencies (SCID)

These are a heterogeneous group of rare (1–2 live births per 100 000), genetically determined disorders resulting from impaired T, NK and B lymphocyte immunity. The most common form of SCID is an X-linked defect in the IL-2 receptor γ chain, interfering with the function of not just IL-2 but also IL-4, IL-7, IL-9 and IL-15 which share this component in their receptors. Clinical features are similar to pure T lymphocyte deficiency and in the blood T and NK cells are lacking whilst B lymphocyte numbers may be normal. The most successful treatment for all forms of SCID is SCT, preferably from HLA-identical donors such as siblings.

Hyper IgM syndrome

This is a milder mixed deficiency, which may not be diagnosed until later in life. It results from an X-linked defect in the CD40 ligand (CD40L (ligand); CD154) gene. Signalling between CD40 on B lymphocytes and CD40L on T lymphocytes is necessary for the generation of class switched B lymphocytes bearing high-affinity immunoglobulin, as well as for the maturation of the T cell response. In CD40L deficiency, B lymphocytes are trapped at the immature level producing only IgM. Levels of other types of immunoglobulin IgG and IgA are absent/low and there are mild defects in T cell function.

Opportunistic infections occur, for example *Pneumocystis*, *Cryptosporidium*, herpes viral infections, *Candida* and *Cryptococcus*.

Wiskott–Aldrich syndrome

This is an X-linked defect (at Xp11–23) in a gene involved in signal transduction and cytoskeletal function with associated eczema and thrombocytopenia; a mainly cell-mediated defect with falling immunoglobulins is seen, and autoimmune manifestations and lymphoreticular malignancy may develop.

Ataxia telangiectasia

These patients have defective DNA repair mechanisms and have cell-mediated defects with low IgA and IgG₂; lymphoid malignancy is again common.

Epstein–Barr Virus (EBV) associated immunodeficiency (Duncan's syndrome)

Apparently normal, but genetically predisposed (usually X-linked) individuals develop overwhelming EBV infection, polyclonal EBV-driven lymphoproliferation, combined immunodeficiency, aplastic anaemia and lymphoid malignancy. EBV appears to act as a trigger for the expression of a hitherto silent immunodeficiency.

B lymphocyte deficiency

X-linked agammaglobulinaemia (XLA)

This presents soon after maternal IgG protection falls, with recurrent infections of the upper and lower respiratory tract with pyogenic organisms, enteritis and malabsorption. Morbidity and mortality are high, mainly due to chronic lung disease and CNS infections with enteroviruses. IgG levels are usually much less than 2.0 g/L (a 1–2-year-old child will usually have an IgG level of 3.5–14 g/L) and all five classes of immunoglobulins are affected, with total levels of less than 2.5 g/L (typically >4 g/L at age 1–2 years). B lymphocyte development is arrested at the pre-B stage and B lymphocytes are absent in the blood. The cause is a loss of function mutation on chromosome Xq22 affecting the gene for a tyrosine kinase involved in cell activation and maturation.

Treatment is by i.v. immunoglobulins (IVIg) to a level that controls infections. Trough IgG concentrations should remain within normal limits (i.e. >5–6 g/L). Prognosis has improved in recent years as more patients survive into adulthood, but chronic lung disease and lymphomas are life-threatening complications.

Selective IgA deficiency

Selective IgA deficiency (IgAD; serum IgA <0.05 g/L), with normal levels of IgG and IgM, is found in approximately 1/600 northern Europeans, making it the most common primary immunodeficiency, although the underlying defect is unknown. Patients typically present at any age with recurrent infections caused by pyogenic organisms and affecting mucosal sites.

Treatment mainly comprises antibiotics. Some IgAD patients produce anti-IgA antibodies of the IgG and IgE class. Infusion of exogenous IgA (e.g. during a blood transfusion) could therefore result in anaphylaxis. IgAD patients should therefore be screened for anti-IgA antibodies, and transfused if necessary with washed red cells, blood from an IgAD donor or with stored aliquots of their own blood.

Common variable immunodeficiency (CVID)

This is a heterogeneous disease affecting 1/50 000 and arising during late childhood and early adulthood, with IgG levels <0.5 g/L. Presenting with recurrent upper and lower respiratory tract infections is typical and may progress to chronic bronchiectatic lung disease, malabsorption and diarrhoea. There may be additional features of T lymphocyte deficiency. Genetic defects underlying the condition have revealed a mutation in the gene encoding ICOS-L (ligand for inducible co-stimulator) on activated T lymphocytes in some cases. IVIg and antibiotics are the treatments of choice.

Defects in antigen presenting cell function

A series of rare genetic defects have been uncovered in which APCs demonstrate an inability to mount protective responses to intracellular bacteria, particularly low virulence mycobacteria and salmonella. The axis affected is the interplay between CD4 T lymphocytes and APCs which drives Th1 responses, and therefore in turn activates mononuclear cells such as macrophages to kill and eradicate intracellular pathogens. Defective genes so far identified include those encoding a component chain of IL-12; a component chain of the IL-12 receptor; and IFN- γ receptor chains 1 or 2.

Neutrophil defects

Chronic granulomatous disease (CGD)

This is a rare (1/250 000) immunodeficiency due to a defect in neutrophil killing and characterized by deep-seated

infections. The functional defect is an inability to generate antibacterial metabolites through the respiratory burst (Table 3.5). Typical onset is at toddler age. Neutrophil numbers are normal or increased. A simple respiratory burst test of neutrophil function is diagnostic.

Treatment of infections and prophylactic antibiotic and antifungal therapy are required. Immunotherapy with interferons may have a role in patients with intractable infections, and in some cases SCT is required.

Leucocyte adhesion deficiency (LAD)

This results from defects in integrins (see p. 23). Numerous underlying defects in the gene encoding one of the component chains, CD18, have been described in LAD-I. LAD-I has an autosomal recessive inheritance presenting almost immediately after birth, with delayed umbilical cord separation. Recurrent infections similar to those in chronic granulomatous disease appear during the first decade of life. Blood neutrophil levels are high but cells are absent from the sites of infection, which require aggressive antimicrobial and antifungal treatment, and SCT for cure.

Hyper IgE syndrome (or Job's syndrome)

This is an autosomal dominant (occasionally sporadic) immune disorder with high serum IgE levels, dermatitis, boils, pneumonias with cyst formation and bone and dental abnormalities. Mutations in *STAT3* have been found.

Shwachman's syndrome

This can resemble cystic fibrosis clinically with exocrine pancreatic insufficiency and pyogenic infections. A mild neutropenia is associated with a defect of neutrophil migration.

Chédiak-Higashi syndrome

This is a rare, recessive disorder due to a mutation in the lysosomal trafficking regulator gene (*LYST*) on chromosome 1q42–45. There are defects in neutrophil function with defective phagolysosome fusion and large lysosome vesicles are seen in phagocytes. Patients have recurrent infections, neutropenia, anaemia and hepatomegaly. Similar abnormalities in melanocytes cause partial oculocutaneous albinism.

Complement deficiency

The consequences of deficiency of complement proteins can be predicted from their functions (Fig. 3.2).

- Failures in innate response components (e.g. the alternative pathway) lead to impaired non-specific immunity with an increase in bacterial infections.
- Genetically determined low levels of mannose binding lectin (MBL) are associated with a number of inflammatory and infectious diseases.
- Failure of the classical pathway results in a tendency towards infection but also towards diseases in which immune complex deposition causes inflammation, such as systemic lupus erythematosus (SLE; e.g. C1 and C4 deficiency), vasculitis and glomerulonephritis.

An unexpected finding is that neisserial infections (e.g. meningitis due to *N. meningitidis*) are often encountered in patients with complement defects of the membrane attack complex.

Complement regulatory proteins

Deficiency of C1 inhibitor (*C1 esterase*) deficiency (see also p. 1211) is relatively rare. Since this enzyme is involved in regulation of several plasma enzyme systems (e.g. the kinin system) and is continuously consumed, a single parental chromosome defect resulting in 50% of normal production

SIGNIFICANT WEBSITE

Allergen nomenclature: <http://www.allergen.org/allergen.aspx>

barely copes with the demand and fails under stress (hence an autosomal dominant effect). As a result, uncontrolled activation of complement and the kinins may occur, leading to oedema of the deep tissues affecting the face, trunk, viscera and the airway, hence the alternative name of hereditary angio-oedema (HAE).

TYPE I HYPERSENSITIVITY AND ALLERGIC DISEASE

Normally host defence can cope with potentially harmful cells and molecules. Under some circumstances, a harmless molecule can initiate an immune response that can lead to tissue damage and death. Such exaggerated, inappropriate responses are termed hypersensitivity reactions or allergic disease.

In Type I (immediate) hypersensitivity, the binding of an antigen to specific IgE bound to its high-affinity receptor on a mast cell surface results in massive and rapid cell degranulation and the inflammatory response outlined on page 53. The antigens involved are typically inert molecules present in the environment (termed allergens; see p. 824).

The immediate effects of allergen exposure are often very florid (**early phase response**). Allergic disorders also have a second phase, occurring a few hours after exposure and lasting up to several days. These '**late phase responses**' (LPR) are mediated by Th2 cells recognizing peptide epitopes of the allergen. Recruitment of eosinophils is often a prominent feature.

From a pathological and therapeutic viewpoint, the LPR gives rise to chronic inflammation which is difficult to control. In *asthma* the LPR gives rise to the prolonged wheezing that can be fatal. Immediate hypersensitivity is usually responsive to antihistamines but the LPR is not, requiring powerful immune modulators such as corticosteroids.

In immunopathological terms, in the LPR:

- Neutrophils and eosinophils are prominent in the first 6–18 hours and may persist for 2–3 days.
- Th2 cells accumulate around small blood vessels and persist for 1–2 days.
- Mediators responsible for the cellular infiltrate include platelet-activating factor and leukotrienes (Table 3.18).
- Th2 cytokines IL-4 and IL-5 and chemokines such as eotaxin act as growth and activation stimuli for eosinophils, which are capable of extensive tissue

damage. Th2 cytokines are also responsible for the class switch of Ig production towards IgE, maintaining the cycle of immediate and late responses.

What makes an allergen so powerful? Several allergens are proteolytic enzymes allowing them to cross skin and mucosal barriers. They are often contained within small, aerodynamic particles (e.g. pollen grains) that gain access to nasal and bronchial mucosa.

Why do some people react and others not? The tendency to develop allergic responses (known as atopy) shows strong heritability. Between 20% and 30% of the UK population is atopic and two, one or no atopic parents pass on the atopic trait to their children with a risk of 75%, 50% and 15%, respectively. In developing nations the tendency to allergy is estimated at one-tenth of the rate in industrialized countries. Amongst the predisposing genes are those encoding the β chain of the high-affinity receptor for IgE and IL-4, both strongly associated with Th2 pathways. The presence of Th2 cells recognizing allergens is the pathological hallmark of allergy.

What environmental factors are involved? Early exposure to allergens (even *in utero*) may be a factor in developing atopy. Over-zealous attention to cleanliness (the hygiene hypothesis) in developed societies (use of antibiotics, reduced exposure to pathogens which might favour a Th1-like environment) may favour a reduction in Treg activity. This environmental factor is shown by the rapid increase of allergy in the Eastern part of Germany following reunification.

In clinical terms, approximately two-thirds of atopic individuals (who can be identified as those with circulating allergen-specific IgE) have clinical allergic disease (equating to 15–20% of the UK population). Allergy accounts for up to one-third of school absences because of chronic illness. Other allergic disorders include allergic rhinitis (hay fever), allergic eczema, bee and wasp venom allergy and some forms of food allergy, urticaria and angio-oedema.

Diagnosis

Diagnosis of allergic disease is usually made on the history and backed up by skin-prick testing (insertion of a tiny quantity of allergen under the skin and measurement of the size of the weal) and/or measurement of allergen-specific IgE. Mast cell tryptase serum levels peak 1–2 hours after an event, remaining high for 24 hours.

Treatment

Avoidance is the first-line of therapy.

- **Antihistamines** are effective for many immediate hypersensitivity reactions (but have no role in the treatment of asthma). A *monoclonal antibody* that mops up serum IgE (omalizumab) is also used (see p. 831).
- **Corticosteroids** have several well-identified modifying actions in the allergic process: production of prostaglandin and leukotriene mediators is suppressed, inflammatory cell recruitment and migration is inhibited and vasoconstriction leads to reduced cell and fluid leakage from the vasculature.
- **Cysteinyl leukotriene receptor antagonists (LTRAs)** inhibit leukotrienes (LTs) by blocking the type I receptor (e.g. montelukast, used in asthma, particularly aspirin induced).
- **Omalizumab** is a monoclonal antibody that binds IgE. It is used in severe asthma that cannot be controlled with a corticosteroid plus a long-acting β_2 agonist. Treatment must be initiated in a specialist centre with experience of treating severe persistent asthma.

Table 3.18 Mediators involved in the allergic response

Preformed mediators
Histamine and serotonin: Bronchoconstriction Increased vascular permeability Neutrophil and eosinophil chemotactic factors (NCF and ECF): Induce inflammatory cell infiltration
Newly formed mediators (membrane-derived)
Leukotriene (LT) B ₄ : Chemoattractant LTC ₄ , -D ₄ , -E ₄ (slow reacting substance of anaphylaxis, SRS-A): Sustained bronchoconstriction and oedema Prostaglandins and thromboxanes: Platelet-activating factor (PAF) Prolonged airway hyperactivity

- **Desensitization (allergen immunotherapy)** can be used. The principle is that allergy can be prevented by inoculation by giving the allergen in a controlled way. It is indicated for disorders in which the hypersensitivity is IgE mediated, e.g. life-threatening allergy to insect stings, drug allergy and allergic rhinitis. An induction course of subcutaneous injections of increasing doses of the allergen extract, given once every 1–2 weeks, is followed by maintenance injections monthly for 2–3 years. A systematic review of 51 published randomized placebo-controlled clinical trials, enrolling a total of nearly 3000 participants, showed a low risk of adverse events with consistent clinical benefit. From an immunological viewpoint, desensitization seems capable of modifying the allergic response at several levels (Table 3.19). Sublingual allergen immunotherapy (using grass pollen extract tablets of Phl p 5 from Timothy grass; see p. 810) is used in hay fever that has not responded to anti-allergic drugs (the first dose is given under medical supervision).

Anaphylaxis

Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death. It arises as an acute, generalized IgE-mediated immune reaction involving specific antigen, mast cells and basophils. The reaction requires priming by the allergen, followed by re-exposure. To provoke anaphylaxis, the allergen must be systemically absorbed, either after ingestion or parenteral injection. A range of allergens that provoke anaphylaxis has been identified (Table 3.20).

Anaphylaxis is rare, and the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse,

laryngeal oedema, airway obstruction and respiratory arrest leading to death:

- Fatal reactions to penicillin occur once every 7.5 million injections.
- Between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million stings, with 60–80 deaths per year in North America, and 5–10 in the UK.

Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth and itchiness. The ensuing effects on the vasculature give vasodilatation and oedema. The consequence of these may be no more than a generalized flush, with urticaria and angio-oedema. More serious sequelae are hypotension, bronchospasm, laryngeal oedema and cardiac arrhythmia or infarction. Death may occur within minutes.

Serum platelet-activating factor (PAF) levels correlate directly with the severity of anaphylaxis whereas PAF acetylhydrolase (the enzyme that inactivates PAF) correlated inversely and was significantly lower in peanut sensitive patients with fatal anaphylactic reactions.

Treatment

Early recognition and treatment are essential (Emergency Box 3.1).

The best treatment is prevention. Avoidance of triggering foods, particularly nuts and shellfish, may require almost obsessive self-discipline. Patient education is necessary and many are instructed in the self-administration of adrenaline (epinephrine) and carry pre-loaded syringes. Desensitization has a well-established place in the management of this disorder, particularly if exposure is unavoidable or unpredictable, as in insect stings.

Type I hypersensitivity and allergic disease

Autoimmune disease

Table 3.19 Mechanism of action of desensitization for allergy

Probable mechanism	Effect
IgG blocking antibodies	During repeated exposure to desensitizing allergen, IgG class antibodies develop (especially IgG4 subclass); these compete with the pathogenic IgE for allergen binding, and/or prevent IgE-allergen complexes binding to mast cell high-affinity IgE receptors
Regulation	Exposure to repeated desensitizing allergen induces Treg cells which recognize allergen but invoke regulatory immune responses, dampening down migration, infiltration and inflammation
Immune deviation	A shift away from Th2- to Th1-producing CD4 cells results in the generation of cytokines (e.g. IFN- γ) which are inhibitory to IgE production

Table 3.20 Sources of allergens known to provoke anaphylaxis

Foods	Nuts: peanuts (protein-arachis hypogaea Ara h 1–3), Brazil, cashew Shellfish: shrimp (allergen Met e 1), lobster Dairy products Egg More rarely: citrus fruits, mango, strawberry, tomato
Venoms	Wasps, bees, yellow-jackets, hornets
Medications	Antisera (tetanus, diphtheria), dextran, latex, some antibiotics

AUTOIMMUNE DISEASE

Autoimmunity is when the immune response turns against self, i.e. recognizes 'self' antigens. The vast array of possible TCRs and antibodies that can be generated by the host make

Emergency Box 3.1

Treatment of acute anaphylaxis

Clinical features:

- Bronchospasm
- Facial and laryngeal oedema
- Hypotension
- Nausea, vomiting and diarrhoea

Management:

- ABCDE (Airway Breathing Circulation Disability Exposure)
 - Position the patient lying flat with feet raised
 - Ensure the airway is free
 - Give oxygen
 - Monitor BP
 - Establish venous access
 - Administer 0.5 mg intramuscular adrenaline (epinephrine) and repeat every 5 min if shock persists.
 - Administer intravenous antihistamine (e.g. 10–20 mg chlorphenamine) slowly
 - Administer 100 mg intravenous hydrocortisone.
- If hypotension persists, give 1–2 L of intravenous fluid. If hypoxia is severe, assisted ventilation may be required. Take blood for tryptase levels (aids diagnosis).

it highly probable that at least a small proportion can recognize self (i.e. are autoreactive). Moreover, a degree of autoreactivity is physiological – the TCR is designed to interact both with the peptide epitope in the HLA molecule binding groove, and with the HLA molecule itself.

The critical event in the development of autoimmune disease is when T and B lymphocytes bearing these receptors become activated. The following are the major checkpoints that the immune system has in place to prevent this:

1. Removal of TCRs with very strong affinity for 'self' in the thymus
2. The presence of naturally arising regulatory T lymphocytes (Tregs)
3. The requirement for a danger signal to license dendritic cells to activate CD4 T lymphocytes.

Autoimmune diseases affect 5% of the population at some stage of their life.

Failure of Checkpoint 1, thymic education

During thymic education, TCRs with dangerously high affinity for self are deleted. It has become apparent that this relies upon the thymic expression of self antigens. Situations which compromise the expression of a self protein would be expected to favour the development of autoimmunity. Indeed, in a rare group of patients who develop multiple autoimmune disorders affecting the adrenal and parathyroid glands (autoimmune polyglandular syndrome type 1; see p. 997), there is a defect in the *AIRE* gene (for autoimmune regulator), which controls thymic expression of a host of self genes. When the gene malfunctions, there is reduced expression of self proteins in the thymus and autoimmune disease is a consequence.

Failure of Checkpoint 2, regulatory T lymphocytes

An example of Treg failure is the defect in the gene encoding Foxp3, a critical transcription factor in Tregs (see p. 61) that leads to IPEX (see p. 61). IPEX is very rare, but it serves to indicate how Treg defects can lead to autoimmune disease. Laboratory studies in this area are revealing subtle Treg defects in several autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis, rheumatoid arthritis).

Failure of Checkpoint 3, CD4 T lymphocyte activation against an autoantigen (or its mimic)

For an autoimmune disease to develop, there must be presentation of autoantigens to a naive, potentially autoreactive CD4 T lymphocyte by activated DCs. This could happen in one of two ways:

- Tissue damage due to infection leads to both the release of hidden self antigens and the provision of sufficient danger signals to activate DCs, which in turn activate autoreactive CD4 T lymphocytes as well as the pathogen-specific ones. This is often termed 'bystander activation'.
- A pathogen mimics a self antigen. In the process of making an entirely appropriate immune response against the pathogen, T or B lymphocytes are generated that also have the capacity to recognize self. This is termed molecular mimicry.

It is unlikely that for the common autoimmune diseases (Table 3.21) there is a 'single checkpoint' explanation. Rather, it is likely that multiple subtle defects, at various checkpoints, are at play.

Table 3.21 Some autoimmune diseases and their autoantigens

Disease	Antigens
Addison disease	21 α -hydroxylase
Goodpasture's syndrome	Type IV collagen (located in GBM)
Graves' thyroiditis	Thyroid-stimulating hormone receptor
Hashimoto's thyroiditis	Thyroid peroxidase, thyroglobulin
Multiple sclerosis	Myelin basic protein Myelin oligodendrocyte glycoprotein
Myasthenia gravis	Acetylcholine receptor
Pemphigus vulgaris	Desmoglein-3
Pernicious anaemia	H ⁺ /K ⁺ -ATPase, intrinsic factor
Polymyositis/dermatomyositis	tRNA synthases
Primary biliary cirrhosis	Pyruvate dehydrogenase complex
Rheumatoid arthritis	Citrullinated cyclic peptide, IgM
Scleroderma	Topoisomerase
Sjögren's syndrome	Ro/La ribonuclear proteins
Systemic lupus erythematosus	Sm/RNP, Ro/La (SS-A/SS-B), histone and native DNA
Type 1 diabetes	Proinsulin, glutamic acid decarboxylase, IA-2, ZNT8
Vitiligo	Pigment cell antigens
Wegener's granulomatosis (Granulomatosis with polyangiitis).	Neutrophil proteinase 3

GBM, glomerular basement membrane.

Mechanisms of tissue damage in autoimmune disease

Figure 3.15 illustrates potential mechanisms of immune damage in autoimmune disease.

Tissue damage via chronic inflammation

In a number of autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis) autoreactive T lymphocytes are likely to be the main drivers of disease and tissue damage. Th1 cells, CTLs and Th17 cells induce chronic inflammation and release cytokines that recruit other effector cells (macrophages) or are directly toxic (e.g. insulin-producing β -cells are susceptible to the combined effects of IL-1 β , IFN- γ and IL-17 in type 1 diabetes).

Tissue damage via autoantibodies

Examples of damage through direct binding to a target cell or structure, with recruitment of complement and other destructive processes, include:

- **myasthenia gravis** (autoantibodies against the acetylcholine receptor cause damage to the neuromuscular junction)
- **autoimmune haemolytic anaemia** (autoantibody targets red blood cell autoantigens leading to lysis)
- **Goodpasture's syndrome** (antiglomerular basement membrane autoantibodies damage glomerular integrity).

Autoantibodies can also bind their antigen in the circulation to form immune complexes. When these are deposited in the tissues, complement and cell-mediated immune reactions are initiated. Immune complexes preferentially deposit in sites such as the kidney glomerulus, leading to chronic kidney disease. This is a feature of SLE, in which the autoantigen within the immune complexes is DNA.

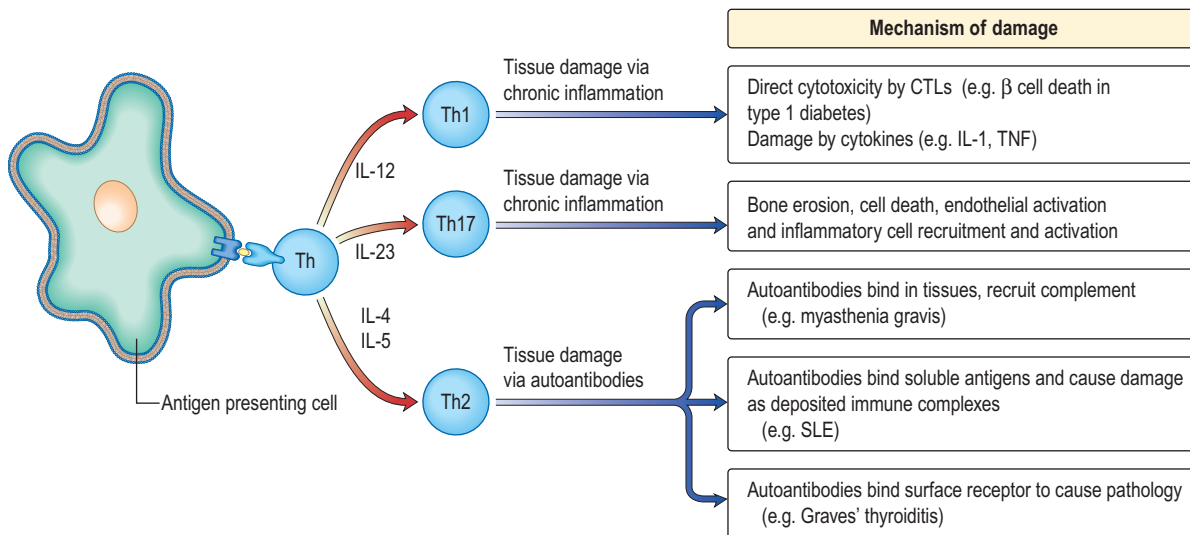

Figure 3.15 Potential mechanisms of immune damage in autoimmune disease.

Table 3.22 Classification of rejection			
Description	Timing of response	Immunological mechanism	Management
Hyperacute	Min–hours	Preformed antibodies (e.g. anti-blood group, anti-HLA)	Prevention
Accelerated acute Acute	1–5 days 7–14 days onwards	T lymphocytes T lymphocytes	Combinations of immune suppression used prophylactically and as required, e.g. corticosteroids, ciclosporin, tacrolimus, sirolimus, polyclonal antibodies (e.g. against all T lymphocytes) and monoclonal antibodies (e.g. against activated T lymphocytes expressing CD25)
Chronic	Months–years	Antibodies, complement, endothelial cell changes	No specific therapy

Autoantibody binding may act by binding to surface receptors. In Graves' thyroiditis, for example, the antithyroid stimulating hormone receptor antibody stimulates follicular cells to produce thyroid hormones, leading to hyperthyroidism.

Common autoimmune diseases

There are now over 80 diseases classified as autoimmune. Some of the diseases are very clear cut in their autoimmune origin, but others are not and both major and minor factors must be defined.

Major criteria

- Evidence of autoreactivity (e.g. activated or memory autoreactive T lymphocytes or autoantibodies)
- Clinical response to immune suppression
- Passive transfer of the putative immune effector (e.g. autoreactive T lymphocyte or autoantibody) causes the disease (hardest criterion to satisfy in man but most stringent).

Minor criteria

- An animal model exists that resembles the human condition, and in which there is a similar loss of immunological tolerance to self
- Evidence that, in the animal model, passive transfer of the putative immune effectors reproduces the disease in a naive animal

- HLA association (frequent indicator that a disease is autoimmune).

ORGAN REJECTION IN CLINICAL TRANSPLANTATION

The outcome of an allograft (i.e. a graft between genetically non-identical members of the same species) in the absence of adequate immunosuppressive therapy is *immunological rejection*. Histological analysis of rejected organs shows a range of immunological processes in action (Table 3.22). With modern tissue-matching approaches, hyperacute rejection is rare and acute rejection can usually be prevented or treated with immunosuppression. The process of chronic rejection typically takes place over several years and is the main reason for organ graft failure.

The antigens recognized in acute and chronic graft responses are donor HLA molecules (alloantigens):

- In acute rejection, it is thought that the predominant response is against intact HLA molecules (*direct allorecognition*) and is mediated by CD4⁺ and CD8⁺ T lymphocytes.
- As the rejection process becomes more chronic, peptides from donor HLA molecules are processed and presented to T lymphocytes by host HLA molecules (*indirect allorecognition*).

IMMUNE-BASED THERAPIES

Manipulating the immune response in a therapeutic setting has seen many successes, as evidenced by the control of organ rejection in clinical transplantation through targeted immunosuppression (Table 3.22). Monoclonal antibodies offer the opportunity to neutralize the unwanted effects of cytokines, or to direct immune responses, drugs, toxins or irradiation against a specific target, whether it be a tumour cell or an immune cell involved in a damaging autoimmune response. Natural antiviral mediators, such as the interferons, are already in the clinic as therapies for, amongst other things, chronic viral infection.

Monoclonal antibody therapy (targeted therapy)

The combined power of monoclonal antibody (MAb) and recombinant DNA technology has led to a series of 'designer' drugs, which have been engineered so that they are:

- (a) exquisitely targeted
- (b) have optimal effector function
- (c) do not carry antigenic segments that may incite a neutralizing response in the host.

In general, this has meant a process of 'humanizing' antibodies of mouse origin and selecting an appropriate effector function. For example, a MAb designed to remove a subpopulation of lymphocytes from the patient should have good complement-fixing ability or bind well to receptors on phagocytes, whereas a MAb designed to 'modulate' a cell without depletion should have these functions removed. An example of the latter is an anti-CD3 MAb that has modified Fc regions and is designed to functionally downregulate, but not deplete, T lymphocytes. Many examples of MAbs in current use are described in individual chapters.

Immunosuppressive drugs

Glucocorticosteroids (cortisone, hydrocortisone, prednisone and prednisolone) are the most commonly used steroids and have a variety of effects on immune function, including:

- potent effects on monocyte production of the pro-inflammatory cytokines IL-1 and TNF- α
- blockade of T lymphocyte production of IL-2 and IFN- γ
- reduced activation and migration of a range of innate and adaptive immune cells.

Ciclosporin, tacrolimus and rapamycin (sirolimus) have similar effects on T lymphocyte function. Ciclosporin and tacrolimus are calcineurin inhibitors and inhibit Ca^{2+} -dependent second messenger signals in T lymphocytes following activation via TCR. By contrast, sirolimus achieves a similar effect but acts at the level of post-activation events in the nucleus.

Purine analogues such as azathioprine are also frequently used as anti-inflammatory drugs in conjunction with steroids

and act by inhibiting DNA synthesis in dividing adaptive immune cells. Similar in mode of action, but more powerful, is mycophenolate mofetil (MMF).

Alkylating agents that interfere with DNA synthesis, such as cyclophosphamide, are also used for immunosuppression.

Cytokines and anticytokines

Cytokines are pleiotropic agents with powerful pro-inflammatory and immunosuppressive effects and are attractive targets for therapies that inhibit or enhance their function. TNF- α targeting agents (cytokine modulators) have been tested in rheumatoid arthritis, as has the recombinant IL-1 receptor antagonist anakinra, although with much less success. Nonetheless, the good safety profile of anakinra has prompted its use in other diseases, and a beneficial effect has been shown in type 2 diabetes, which may have an innate inflammatory component. IL-2 and its receptor (CD25) are also obvious candidates for immune therapies. Interferons are successfully used to boost pro-inflammatory immunity in chronic virus infection.

Restoring tolerance in autoimmune diseases and allergy

One of the goals for immune-based therapies for autoimmune disease is not to simply achieve immunosuppression, but also to restore immunological tolerance against the relevant autoantigens. In animal models an effective means of achieving this is to administer the autoantigen itself, or key peptide epitopes from it. This is known as antigen-specific or peptide immunotherapy and is under trial in several autoimmune diseases, where it appears to induce Tregs. The diseases that have the most advanced clinical data are in the field of allergy. For example, administration of cocktails of peptides of the cat allergen Fel d 1 has led to a reduction in detectable skin-prick responses and improved clinical scores.

Intravenous immunoglobulin

Intravenous immunoglobulin (IVIg) is a preparation of polyspecific IgG chemically purified from the plasma of large numbers (>20 000) of healthy donors. IVIg is used as a replacement therapy in patients with primary and secondary antibody deficiencies. However, when used for inflammatory conditions there is also a therapeutic benefit, although randomized placebo-controlled studies are few. In the USA, IVIg is only recommended for a small number of diseases in addition to antibody deficiency. These include: immune-mediated thrombocytopenia, Kawasaki's syndrome, chronic inflammatory demyelinating polyneuropathy and post-transfusion purpura.

The mechanism of action is not known, but may include:

- Blockade of Fc receptors to prevent pathogenic antibodies binding to phagocytes
- Inhibition of autoantibody synthesis by B lymphocytes
- Inhibition of complement activation
- Induction of T cell regulation.

INFECTION AND INFECTIOUS DISEASE

'Infection' is defined as the process of foreign organisms invading and multiplying in or on a host. In practice, the term is usually reserved for situations in which this results in harm, rather than an infectious agent simply colonizing the host without ill effect. Infectious diseases remain the main cause of morbidity and mortality in man, particularly in developing

areas where they are associated with poverty and overcrowding.

In the **developed world** increasing prosperity, universal immunization and antibiotics have reduced the prevalence of infectious disease. However, antibiotic-resistant strains of microorganisms and diseases such as human

immunodeficiency virus (HIV) infection, variant Creutzfeldt–Jakob disease (vCJD), avian influenza and pandemic H1N1 influenza have emerged. There is increased global mobility, both enforced (as a result of war, civil unrest and natural disaster) and voluntary (for tourism and economic benefit). This has aided the spread of infectious disease and allowed previously localized pathogens such as dengue and West Nile virus to establish themselves across much wider territories. An increase in the movement of livestock and animals has enabled the spread of zoonotic diseases like monkeypox, while changes in farming and food-processing methods have contributed to an increase in the incidence of food- and water-borne diseases. Deteriorating social conditions in the inner city areas of our major conurbations have facilitated the resurgence of tuberculosis and other infections. Prisons and refugee camps, where large numbers of people are forced to live in close proximity, often in poor conditions, are providing a breeding ground for devastating epidemics of infectious disease. There are new concerns about the deliberate release of infectious agents such as smallpox or anthrax by terrorist groups or national governments.

In the **developing world** successes such as the eradication of smallpox have been balanced or outweighed by the new plagues. Infectious diseases cause nearly 25% of all human deaths (Table 4.1), rising to more than 50% in low income countries. Two billion people – one-third of the world's population – are infected with tuberculosis (TB), up to 400 million people catch malaria every year and 200 million are infected with schistosomiasis. Some 500 million people are chronically infected with a hepatitis virus (either HBV or HCV) and 34 million people are living with HIV/AIDS, with 2.6 million new HIV infections in 2008 (65% in sub-Saharan Africa). Infections are often multiple and there is synergy both between different infections and between infection and other factors such as malnutrition. Many of the infectious diseases affecting developing countries are preventable or treatable, but continue to thrive owing to lack of money and political will.

The WHO has set eight Millennium Development Goals (MDGs), to be achieved by 2015: these include combating HIV/AIDS, malaria and other diseases. Currently, nine African and 29 non-African countries are on course to meet the malaria targets and the global incidence of TB is slowly falling. New HIV infections fell by 16% between 2000 and 2008 and antiretroviral treatment provision in low and middle income countries increased 10-fold between 2003 and 2008. A public/private partnership, the Global Fund, was established to combat AIDS, tuberculosis and malaria and has

achieved much by providing the means for treatment for TB, insecticide-treated bed nets for malaria and antivirals for HIV. Several other funding streams (governmental, non-governmental and charitable) have also contributed to the fight against infection.

The impact of global warming on the spread of infection remains uncertain but may be significant. Both natural climatic events and the gradual global change in weather conditions can affect the spread and transmission of infectious diseases. Changes in temperature may directly influence the behaviour of insect vectors, while changes in rainfall may have an effect on water-borne disease. Climate change may also trigger population movement and migration, indirectly affecting infection transmission.

Infectious agents

The causative agents of infectious diseases can be divided into four groups:

Prions are the most recently recognized and the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information: their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrP^C into an abnormal protease-resistant isoform referred to as PrP^{Sc}.

Viruses contain both protein and nucleic acid and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on 'hijacking' the cellular machinery of the host. They are small (usually less than 250 nanometres (nm) in diameter) and each virus possesses only one species of nucleic acid (either RNA or DNA).

Bacteria are usually, though not always, larger than viruses. Unlike the latter they have both DNA and RNA, with the genome encoded by DNA. They are enclosed by a cell membrane and even bacteria which have adopted an intracellular existence remain enclosed within their own cell wall. Bacteria are capable of fully autonomous reproduction and the majority are not dependent on host cells.

Eukaryotes are the most sophisticated infectious organisms, displaying subcellular compartmentalization. Different cellular functions are restricted to specific organelles, e.g. photosynthesis takes place in the chloroplasts, DNA transcription in the nucleus and respiration in the mitochondria. Eukaryotic pathogens include unicellular protozoa, fungi (which can be unicellular or filamentous) and multicellular parasitic worms.

Other higher classes, notably the insects and the arachnids, also contain species which can parasitize man and cause disease: these are discussed in more detail on page 160.

Host–organism interactions

Each of us is colonized with huge numbers of microorganisms (10^{14} bacteria, plus viruses, fungi, protozoa and worms) with which we co-exist. The relationship with some of these organisms is symbiotic, in which both partners benefit, while others are commensals, living on the host without causing harm. Infection and illness may be due to these normally harmless commensals and symbiotes evading the body's defences and penetrating into abnormal sites. Alternatively, disease may be caused by exposure to exogenous pathogenic organisms which are not part of our normal flora.

Table 4.1 Worldwide mortality from infectious diseases

Disease	Estimated deaths (annual)
Acute lower respiratory infection	3.5 million
HIV/AIDS	2 million
Tuberculosis	2 million
Diarrhoeal disease	1.8 million
Malaria	1 million
Measles	350 000
Whooping cough	301 000
Tetanus	292 000
Meningitis	175 000
Leishmaniasis	51 000
Trypanosomiasis	10 000

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely due to killing of host cells by the invading organism. Usually, however, the harmful effects of infection are due to a combination of direct microbial pathogenicity and the body's response to infection. In meningococcal septicaemia, for example, much of the tissue damage is caused by cytokines released in an attempt to fight the bacteria. The molecular mechanisms underlying host-pathogen interactions are discussed in more detail on [page 78](#).

Sources of infection

The endogenous skin and bowel commensals can cause disease in the host, either because they have been transferred to an inappropriate site (e.g. bowel coliforms causing urinary tract infection) or because host immunity has been attenuated (e.g. candidiasis in an immunocompromised host). Many infections are acquired from other people, who may be symptomatic themselves or be asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals, but cause invasive disease in a small minority of those colonized. Infection with other organisms, such as the hepatitis B virus, can be followed in some cases by an asymptomatic but potentially infectious carrier state.

Zoonoses are infections that can be transmitted from wild or domestic animals to man. Infection can be acquired in a number of ways: direct contact with the animal, ingestion of meat or animal products, contact with animal urine or faeces,

aerosol inhalation, via an arthropod vector or by inoculation of saliva in a bite wound. Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in [Table 4.2](#).

Most microorganisms do not have a vertebrate or arthropod host but are free-living in the environment. The vast majority of these environmental organisms are non-pathogenic, but a few can cause human disease ([Table 4.3](#)). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle which is environmental (e.g. the free-living larval stage of *Strongyloides stercoralis* and the hookworms), even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and be transmitted from host to host via this route (see below): these should not be confused with true environmental organisms.

Routes of transmission

Endogenous infection

The body's own endogenous flora can cause infection if the organism gains access to an inappropriate area of the body. This can happen by simple mechanical transfer, e.g. colonic bacteria entering the female urinary tract. The nonspecific host defences may be breached, for example, by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is frequently the aetiology of cellulitis. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora to produce invasive disease.

Table 4.2 Zoonotic infections

Disease	Pathogen	Animal reservoir	Mode of transmission
Prions			
vCJD	Prion protein	Cattle	Ingestion (CNS tissue)
Viral			
Lassa fever	Arenavirus	Multimammate rat	Direct contact
Avian influenza	Influenza H5N1	Birds	Inhalation
Japanese encephalitis	Flavivirus	Pigs	Mosquito bite
Rabies	Rhabdovirus	Dog and other mammals	Saliva, faeces (bats)
Yellow fever	Flavivirus	Primates	Mosquito bite
Monkeypox	Orthopox virus	Rodents, small mammals	Uncertain
SARS	Coronavirus	Unsure, most likely bats	Droplet
Bacterial			
Gastroenteritis	<i>Escherichia coli</i> 0157 <i>Salmonella enteritidis</i> and others <i>Campylobacter jejuni</i>	Cattle, chickens Chickens, cattle Various, e.g. chicken	Ingestion (contaminated food) Ingestion (meat, eggs) Ingestion (meat, milk, water)
Leptospirosis	<i>Leptospira interrogans</i>	Rodents	Ingestion (urine)
Brucellosis	<i>Brucella abortus</i> <i>Brucella melitensis</i>	Cattle Sheep, goats	Contact; ingestion of milk/cheese
Anthrax	<i>Bacillus anthracis</i>	Cattle, sheep	Contact; ingestion
Lyme disease	<i>Borrelia burgdorferi</i>	Deer	Tick bite
Cat-scratch disease	<i>Bartonella henselae</i>	Cats	Flea bite
Plague	<i>Yersinia pestis</i>	Rodents	Flea bite
Typhus	Various <i>Rickettsia</i> spp.	Various	Arthropod bite
Psittacosis (ornithosis)	<i>Chlamydia psittaci</i>	Psittacine and other birds	Aerosol
Others			
Toxoplasmosis	<i>Toxoplasma gondii</i>	Cats and other mammals	Ingestion (meat, faeces)
Hydatid disease	<i>Echinococcus granulosus</i>	Dogs	Ingestion (faeces)
Trichinosis	<i>Trichinella spiralis</i>	Pigs, bears	Ingestion (meat)
Toxocariasis	<i>Toxocara canis</i>	Dogs	Ingestion
Cutaneous larva migrans	<i>Ancylostoma caninum</i>	Dogs	Penetration of skin by larvae
Leishmaniasis	<i>Leishmania</i> spp.	Dogs	Ingestion

vCJD, variant Creutzfeldt-Jakob disease; SARS, severe acute respiratory syndrome.

Table 4.3 Environmental organisms which can cause human infection

Organism	Disease (most common presentations)
Bacteria	
<i>Burkholderia pseudomallei</i>	Melioidosis
<i>Burkholderia cepacia</i>	Lung infection in cystic fibrosis
<i>Pseudomonas</i> spp.	Various
<i>Legionella pneumophila</i>	Legionnaires' disease (pneumonia)
<i>Bacillus cereus</i>	Gastroenteritis
<i>Listeria monocytogenes</i>	Various
<i>Clostridium tetani</i>	Tetanus
<i>Clostridium perfringens</i>	Gangrene, septicaemia
Mycobacteria other than tuberculosis (MOTT)	Pulmonary infections
Fungi	
<i>Candida</i> spp.	Local and disseminated infection
<i>Cryptococcus neoformans</i>	Meningitis, pulmonary infection
<i>Histoplasma capsulatum</i>	Pulmonary infection
<i>Coccidioides immitis</i>	Pulmonary infection
<i>Mucor</i> spp.	Mucormycosis (rhinocerebral, cutaneous)
<i>Sporothrix schenckii</i>	Lymphocutaneous sporotrichosis
<i>Blastomyces dermatitidis</i>	Pulmonary infection
<i>Aspergillus fumigatus</i>	Pulmonary infections

Air-borne spread

Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed or breathed out and are then inhaled by a new victim. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens such as *Legionella pneumophila* and zoonoses such as psittacosis, are also acquired by aerosol inhalation, while rabies virus may be inhaled in the dust from bat droppings.

Faeco-oral spread

Transmission of organisms by the faeco-oral route can occur by direct transfer (usually in small children), by contamination of clothing or household items (usually in institutions or conditions of poor hygiene) or most commonly via contaminated food or water. Human and animal faecal pathogens can get into the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation, or serving of foodstuffs. In the western world, the centralization of food supply and increased processing of food has allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of food-borne infection.

Water-borne faeco-oral spread is usually the result of inadequate access to clean water and safe sewage disposal and is common throughout the developing world. Worldwide, 1.1 billion people have no access to clean water and 2.6 billion do not have basic sanitation.

Vector-borne disease

Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate

Table 4.4 Infections transmitted by arthropod vectors

Vector	Disease	Microorganism
Mosquito	Malaria	<i>Plasmodium</i> spp.
	Lymphatic filariasis	<i>Wuchereria bancrofti</i> , <i>Brugia malayi</i>
	Yellow fever	Flavivirus
	West Nile fever	Flavivirus
	Dengue	Flavivirus
Sandfly	Leishmaniasis	<i>Leishmania</i> spp.
Blackfly	Onchocerciasis	<i>Onchocerca volvulus</i>
Tsetse fly	Sleeping sickness	<i>Trypanosoma brucei</i>
Flea	Plague	<i>Yersinia pestis</i>
	Endemic typhus	<i>Rickettsia typhi</i>
	Carrion's disease	<i>Bartonella bacilliformis</i>
Reduviid bug	Chagas' disease	<i>Trypanosoma cruzi</i>
Louse	Epidemic typhus	<i>Rickettsia prowazekii</i>
	Louse-borne relapsing fever	<i>Borrelia recurrentis</i>
Hard tick	Lyme disease	<i>Borrelia burgdorferi</i>
	Typhus (spotted fever group)	<i>Rickettsia</i> spp.
	Babesiosis	<i>Babesia</i> spp.
	Tick-borne relapsing fever	<i>Borrelia duttonii</i>
	Tick-borne encephalitis	Flavivirus
	Congo-Crimean haemorrhagic fever	Nairovirus (Bunyavirus)

climates, but are relatively uncommon. In most cases part of the parasite life cycle takes place within the body of the arthropod and each parasite species requires a specific vector. Simple mechanical transfer of infective organisms from one host to another can occur, but is rare. Some vector-borne diseases are shown in Table 4.4.

Direct person-to-person spread

Organisms can be passed on directly in a number of ways. Sexually transmitted infections are dealt with on page 160. Skin infections such as ringworm, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by blood- (or occasionally other body fluid) to-blood transmission. Blood-to-blood transmission can occur during sexual contact, from mother to infant either transplacentally or in the peripartum, between intravenous drug users sharing any part of their injecting equipment, when infected medical or other (e.g. tattoo needles) equipment is reused, if contaminated blood or blood products are transfused, or in any sporting or accidental contact when blood is spilled. Ingestion of infected breast milk is another route of person-to-person spread for some infections (e.g. HIV).

Direct inoculation

Infection can occur when pathogenic organisms breach the normal mechanical defences by direct inoculation. Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission above. Some environmental organisms may be inoculated by accident: this is a common mode of transmission of tetanus and certain fungal infections. Rabies virus may be inoculated by the bite of an infected animal.

Consumption of infected material

Although many food-related zoonotic infections are due to contamination of food with animal faeces (and are thus, strictly speaking, faeco-oral), several diseases are transmitted directly in animal products. These include some strains of *Salmonella* (eggs, chicken meat), brucellosis (unpasteurized milk) *E. coli* and the prion diseases kuru and vCJD (neural tissue).

Prevention and control

Methods of preventing infection depend upon the source and route of transmission, as described above.

- **Infection control measures.** Poor infection control practice in hospitals and other healthcare environments can cause the transfer of infection from person to person. This may be air-borne, via fomites or a direct contact route. It is essential that all healthcare workers wash or clean their hands before and after patient contact and whenever necessary they should wear gloves, aprons and other protective equipment. This is particularly necessary when performing invasive procedures, or manipulating indwelling devices such as cannulae.
- **Eradication of reservoir.** In a few diseases, for which man is the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case finding, **treatment and immunization**. This has been achieved in the case of smallpox. If there is an animal or environmental reservoir, complete eradication is unlikely, but local control methods may decrease the risk of human infection (e.g. killing of rodents to control plague, leptospirosis and other diseases).
 - For **arthropod–vector-borne infections**:
 - destroying vector species (which may be practical in certain circumstances)
 - taking measures to avoid being bitten (e.g. insect repellent sprays, impregnated bed nets).
 - For **food-borne infections**. Improvements in food handling and preparation result in less contamination during processing, transport or preparation. Organisms intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public, is necessary.
 - For **faeco-oral infections**. Improvements in water supply and sanitation (recognized in the Millennium Development Goals) could dramatically decrease the prevalence of faeco-oral infections.
 - For **blood-borne infections**. Prevention of blood transfer, e.g. in blood transfusions and contaminated medical equipment. Donated blood is routinely tested for infection in most developed countries.
 - For **infections spread by air-borne and direct contact**. Some air-borne-transmitted respiratory infections and some infections spread by direct contact can be controlled by isolating patients. This is often difficult, but isolation is useful in patients with severe immunodeficiency to protect them from infection.
- **Immunization** (see p. 94).

Healthcare-associated infections (HCAI)

In recent years, the burden of morbidity, mortality and cost attributed to healthcare-associated infection has been

highlighted in many developed countries. Although data from low income countries are lacking the impact of HCAI is likely to be even greater. *Clostridium difficile*, *Staphylococcus aureus* (especially MRSA), vancomycin-resistant enterococci and multiresistant Gram-negative organisms are all strongly associated with healthcare contact and are an increasing problem in hospitals worldwide. In the UK, the Department of Health estimates the risk of acquiring HCAI in a healthcare facility to be 6–10%, with HCAs costing the NHS up to £1 billion per year. The response to HCAs needs to be multifaceted. High standards of basic infection control (isolation, barrier precautions, hand hygiene and cleaning) need to be combined with decreased use of invasive devices such as vascular cannulae and urinary catheters, with better insertion and care standards when these are used. Antibiotic stewardship, with reduced overall usage and restriction of broad-spectrum agents, is essential to minimize antimicrobial resistance. There are already data to suggest that reduction in the use of cephalosporins has reduced the incidence of *C. difficile*. Often a combination of different methods can be used together to reduce a particular risk (e.g. ventilator-associated pneumonia): the so-called ‘care bundle’ approach.

Classification of outbreaks

The type of outbreak has a bearing on public health measures that need to be instituted for its control.

- **Person to person** where infection is passed from one infected individual to another and outbreaks of infection are separated by the incubation period.
- **‘Point source’** is where there is a single source of infection, e.g. food eaten at a social function. All those infected will develop symptoms at the same time, around the expected incubation period.
- **Common source** where there is a single source of infection but over a period of time, e.g. a symptomatic carrier of infection working with food preparation. Many people will be exposed over a long period of time.
- **Epidemic**. An increased unusual widespread infection in the community, causing waves of infection. These spread through communities and affect all people who have no active immunity to that infection.

Cases of some infectious diseases should be notified to the public health authorities so that they are aware of cases and outbreaks. Diseases that are notifiable in England and Wales are listed in Table 4.5.

Table 4.5 Diseases notifiable (to Local Authority Proper Officers) in England and Wales, under the Health Protection (Notification) Regulations 2010

Acute encephalitis	Meningococcal septicaemia (without meningitis)
Acute meningitis	Mumps
Acute poliomyelitis	Plague
Acute infectious hepatitis	Rabies
Anthrax	Rubella
Botulism	SARS
Cholera	Smallpox
Diphtheria	Tetanus
Food poisoning	Tuberculosis
Haemolytic uraemic syndrome (HUS)	Typhus
Leprosy	Viral haemorrhagic fever
Leptospirosis	Viral hepatitis
Malaria	Whooping cough
Measles	Yellow fever
Meningitis	

Five moments for hand hygiene

1. Before touching patient
2. Before clean/aseptic procedures
3. After body-fluid exposure risk
4. After touching patient
5. After touching patient surroundings

Five moments for hand hygiene.

Water collection.

PRINCIPLES AND BASIC MECHANISMS

Man constantly interacts with the world of microorganisms from birth to death. The majority cause no harm and some play a role in the normal functioning of the mouth, vagina and intestinal tract. However many microorganisms have the potential to produce disease. This may result from inoculation into damaged tissues, tissue invasion, a variety of virulence factors, or toxin production.

Specificity

Microorganisms are often highly specific with respect to the organ or tissue they infect (Fig. 4.1). For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E and yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types and partly to the immediate environment in which the organism finds itself; e.g. anaerobic organisms colonize the anaerobic colon, whereas aerobic organisms are generally found in the mouth,

pharynx and proximal intestinal tract. Other organisms that show selectivity include:

- *Streptococcus pneumoniae* (respiratory tract)
- *Escherichia coli* (urinary and alimentary tract).

Even within a species of bacterium such as *E. coli*, there are clear differences between strains with regard to their ability to cause gastrointestinal disease (see p. 110), which in turn differ from uropathogenic *E. coli* responsible for urinary tract infection.

Within an organ a pathogen may show selectivity for a particular cell type. In the intestine, for example, rotavirus predominantly invades and destroys intestinal epithelial cells on the upper portion of the villus, whereas reovirus selectively enters the body through the specialized epithelial cells, known as M cells that cover the Peyer's patches (see p. 262).

Pathogenesis

Figure 4.2 summarizes some of the steps that occur during the pathogenesis of infection. In addition, pathogens have developed a variety of mechanisms to evade host defences.

Figure 4.1 Sites of infection with common organisms.

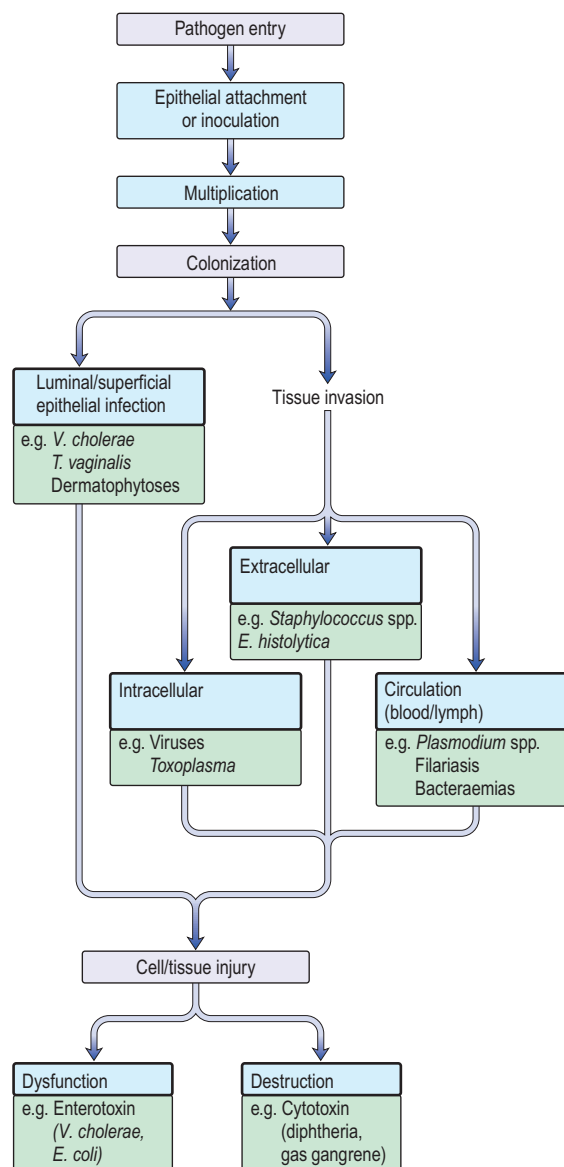

Figure 4.2 The pathogenesis of infection.

For example, some pathogens produce toxins directed at phagocytes: *Staphylococcus aureus* (α -toxin), *Streptococcus pyogenes* (streptolysin) and *Clostridium perfringens* (α -toxin), while others such as *Salmonella* spp. and *Listeria monocytogenes* can survive within macrophages. Several pathogens possess a capsule that protects against complement activation (e.g. *Strep. pneumoniae*). Antigenic variation is an additional mechanism for evading host defences that is recognized in viruses (antigenic shift and drift in influenza), bacteria (flagella of *salmonella* and gonococcal pili) and protozoa (surface glycoprotein changes in *Trypanosoma*).

Epithelial attachment

Many bacteria attach to the epithelial substratum by specific organelles called pili (or fimbriae) that contain a surface lectin(s) – a protein or glycoprotein that recognizes specific sugar residues on the host cell. This family of molecules is known as adhesins (see p. 23). Following attachment, some bacteria, such as species of coagulase-negative staphylococci, produce an extracellular slime layer and recruit additional bacteria, which cluster together to form a biofilm. These biofilms can be difficult to eradicate and are a frequent

cause of medical device-associated infections which affect prosthetic joints and heart valves as well as indwelling catheters. Many viruses and protozoa (e.g. *Plasmodium* spp., *Entamoeba histolytica*) attach to specific epithelial target-cell receptors. Other parasites such as hookworm have specific attachment organs (buccal plates) that firmly grip the intestinal epithelium.

Colonization

Following epithelial attachment pathogens may remain either on the surface epithelium or within the lumen of the organ they have colonized. Tissue invasion may follow.

Invasion may result in:

- an intracellular location for the pathogen (e.g. viruses, *Mycobacterium* spp., *Toxoplasma gondii*, *Plasmodium* spp.)
- an extracellular location for the pathogen (e.g. pneumococci, *E. coli*, *Entamoeba histolytica*)
- invasion directly into the blood or lymph circulation (e.g. schistosome schistosomula and trypanosomes).

Once the pathogen is firmly established in its target tissue, a series of events follows that usually culminates in damage to the host.

Tissue dysfunction or damage

Microorganisms produce disease by a number of well-defined mechanisms:

Cell lysis

The presence of replicating viruses within a cell may interfere with host cell metabolism such that the cell dies – so-called cytolytic or cytotoxic infection.

Exotoxins and endotoxins

- **Exotoxins** have many diverse activities including inhibition of protein synthesis (diphtheria toxin), neurotoxicity (*Clostridium tetani* and *C. botulinum*) and enterotoxicity, which results in intestinal secretion of water and electrolytes (*E. coli*, *Vibrio cholerae*). Colonization and secretion in many classical diarrhoeal diseases is the result of virulence-associated genes which encode protein secretion systems (Fig. 4.3).
- **Endotoxin** is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It is responsible for many of the features of septic shock (see p. 881), namely hypotension, fever, intravascular coagulation and, at high doses, death. The effects of endotoxin are mediated predominantly by release of tumour necrosis factor.

Staphylococcus aureus presents an excellent example of the repertoire of microbial virulence. The clinical expression of disease varies according to site, invasion and toxin production and is summarized in Table 4.6. Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing and metabolic disturbances (Table 4.7).

Host response to infection

Natural defences

The natural host defences to infection are those of an intact surface epithelium with local production of secretions, antimicrobial enzymes (e.g. lysozyme in the eye) and in the stomach, gastric acidity. The mucociliary escalator of the large airways is unique to the lung.

Figure 4.3 Protein secretion pathways for Gram-negative bacteria. These specialized pathways are necessary for virulence. Types I and II facilitate protein (toxin) secretion into the extracellular space (Type I). Type II does this in two stages. Types III and IV pathways secrete toxins as well as inject toxins directly into the host cells via multiprotein complexes across the bacterial cell envelope and host cell membrane. Type V is a minor variation of Type II. Type VI pathway is unclear but is involved in cytotoxicity. (Reproduced with permission from Yarh TL. A critical new pathway for toxin secretion? Immunological defences

Antibody and cell-mediated immune mechanisms play a vital role in combating infection. All organisms can initiate secondary immunological mechanisms, such as complement activation, immune complex formation and antibody-mediated cytotoxicity of cells. The immunological response to infection is described in [Chapter 3](#).

Metabolic and immunological consequences of infection

Fever

Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus in the floor of the third ventricle. Body temperature is maintained at 36.8°C in health,

with a diurnal variation of $\pm 0.5^\circ\text{C}$. Gram-negative bacteria contain lipopolysaccharide (LPS) and peptidoglycan, which is also a component of Gram-positive bacterial cell walls. Toll-like receptors (TLR, see [p. 55](#)) on monocytes and dendritic cells recognize these lipopolysaccharides and generate signals leading to formation of inflammatory cytokines, e.g. IL-1, -6, -12, TNF- α and many others. These cytokines act on the thermoregulatory centre by increasing prostaglandin (PGE₂) synthesis. The antipyretic effect of salicylates is brought about, at least in part, through its inhibitory effects on prostaglandin synthase.

Fever production has a positive effect on the course of infection. However, for every 1°C rise in temperature, there is a 13% increase in resting metabolic rate and oxygen consumption. Fever therefore, leads to increased energy

requirements at a time when anorexia leads to decreased food intake. The normal compensatory mechanisms in starvation (e.g. mobilization of fat stores) are inhibited in acute infections. This leads to an increase in skeletal muscle breakdown, releasing amino acids, which, via gluconeogenesis, are used to provide energy.

The inflammatory response

The inflammatory response is a fundamental biological response to a variety of stimuli including microorganisms or their products, such as endotoxin which acts on monocytes and macrophages. Non-phagocytic cells (lymphocytes, natural killer cells) are also involved. The release of cytokines, notably TNF- α , IL-1, IL-6 and interferon- γ , leads to the release of a cascade of other mediators involved in inflammation and tissue remodelling, such as interleukins, prostaglandins, leukotrienes and corticotropin. TNF is therefore responsible for many of the effects of an infection.

The biological behaviour of the pathogen and the consequent host response are responsible for the clinical expression of disease that often allows clinical recognition. The incubation period following exposure can be helpful (e.g. chickenpox 14–21 days). The site and distribution of a rash may be diagnostic (e.g. shingles), while symptoms of cough, sputum and pleuritic pain point to lobar pneumonia. Fever and meningismus characterize classical meningitis. Infection may remain localized or become disseminated and give rise to the sepsis syndrome and disturbances of protein metabolism and acid–base balance (see Ch. 16). Many infections are self-limiting and immune and non-immune host defence mechanisms will eventually clear the pathogens. This is generally followed by tissue repair, which may result in complete resolution or leave residual damage.

APPROACH TO THE PATIENT WITH A SUSPECTED INFECTION

Infectious diseases can affect any organ or system and can cause a wide variety of symptoms and signs. Fever is often regarded as the cardinal feature of infection, but not all febrile illnesses are infections and not all infectious diseases present with a fever. History-taking and examination should aim to identify the site(s) of infection and also the likely causative organism(s).

History

A detailed history is taken with specific questions about epidemiological risk factors for infection. These are based on the sources of infection and routes of transmission discussed above.

- **Travel history:** some diseases are more prevalent in certain geographical locations and many infections common in the tropics are seen rarely, if at all, in the UK.
- **Food and water history:** systemic as well as gastroenteric infections can be caught via this route.
- **Occupational history.**
- **Animal contact:** domestic, farm and wild animals can all be responsible for zoonotic infection.
- **Sexual activity:** as well as the traditional sexually transmitted diseases, HIV, hepatitis B and occasionally other blood-borne infections can be transmitted sexually. Some enteric infections are more common among men who have sex with men.

- **Intravenous drug use:** as well as blood-borne viruses, drug injectors are susceptible to a variety of bacterial and fungal infections due to inoculation. Other needle exposures, such as tattooing and body piercing and receipt of blood products (especially outside the UK), are also risk factors for blood-borne viruses.
- **Leisure activities:** certain pastimes may predispose to water-borne infections or zoonoses.

Clinical examination

A thorough examination covering all systems is required. Skin rashes and lymphadenopathy are common features of infectious diseases and the ears, eyes, mouth and throat should also be inspected. Infections commonly associated with a rash are listed in Box 4.1. Rectal, vaginal and penile examination is required in sexually transmitted infections. The fever pattern may occasionally be helpful, e.g. the tertian fever of falciparum malaria, but too much weight should not be placed on the pattern or degree.

Investigations

In some infections, such as chickenpox, the clinical presentation is so distinctive that no investigations are normally necessary to confirm the diagnosis. Other cases require further tests to determine the cause and site of the infection.

Box 4.1 Infections commonly associated with a rash

Macular/maculopapular

- Measles
- Rubella
- Enteroviruses
- Human herpesvirus 6
- Epstein–Barr virus
- Cytomegalovirus
- Human erythrovirus (parvovirus) B19
- Human immunodeficiency virus (HIV)
- Dengue
- Typhoid
- Secondary syphilis
- Rickettsiae spotted fevers

Vesicular

- Chickenpox (varicella zoster virus)
- Shingles (varicella zoster virus)
- Herpes simplex virus
- Hand, foot and mouth disease (Coxsackie virus, enterovirus 71)
- Herpangina (Coxsackie virus)

Petechial/haemorrhagic

- Meningococcal septicaemia
- Any septicaemia with disseminated intravascular coagulation (DIC)
- Rickettsiae
- Viruses (see Table 4.23)

Erythematous

- Scarlet fever
- Lyme disease (erythema chronicum migrans)
- Toxic shock syndrome
- Human erythrovirus (parvovirus) B19

Urticarial

- *Toxocara*
- *Strongyloides*
- *Schistosoma*
- Cutaneous larva migrans

Others

- Tick typhus (eschar)
- Primary syphilis (chancre)
- Anthrax (ulcerating papule)

Approach to the patient with a suspected infection

Skin rashes and lymphadenopathy are common nonspecific features of infectious diseases.

General investigations (to assess health and identify organ(s) involved)

These will vary depending on circumstances:

- **Blood tests.** Routine blood count, ESR and C-reactive protein (CRP), biochemical profile, urea and electrolytes are performed in the majority of cases. CRP is a nonspecific marker of inflammation and is raised in many different infections: it is more useful in monitoring response to treatment than in making a diagnosis. Procalcitonin may be a more specific marker of bacterial infection, but this remains to be confirmed (Box 4.2).
- **Imaging.** X-ray, ultrasound, echocardiography, CT and MR scanning are used to identify and localize infections. Positron emission tomography (PET) and single photon emission tomography (SPECT) have proved useful in localizing infection, especially when combined with CT scanning. However, the sensitivity and specificity of these tests in diagnosing infection has yet to be determined and their use remains limited. Biopsy or aspiration of tissue for microbiological examination may also be facilitated by ultrasound or CT guidance.
- **Radionuclide scanning** after injection of indium- or technetium-labelled white cells (previously harvested from the patient) may occasionally help to localize infection. It is most effective when the peripheral white cell count is raised and is of particular value in localizing occult abscesses.

Microbiological investigations (to identify causative organism)

Diagnostic services range from simple microscopy to molecular probes. It is often helpful to discuss the clinical problem with a microbiologist to ensure that appropriate tests are performed and that specimens are collected and transported correctly.

Box 4.2 General investigations for a patient with suspected infection

Investigation	Possible cause
Full blood count	
Neutrophilia	Bacterial infection
Neutropenia	Viral infection Brucellosis Typhoid Typhus Overwhelming sepsis
Lymphocytosis	Viral infection
Lymphopenia	HIV infection (not specific)
Atypical lymphocytes	Infectious mononucleosis
Eosinophilia	Invasive parasitic infection
Thrombocytopenia	Overwhelming sepsis Malaria
ESR or C-reactive protein	Elevated in many infections
Urea and electrolytes	Potentially deranged in severe illness from any cause
Procalcitonin	Elevated particularly in bacterial infection
Liver enzymes	
Minor elevation of transferases	Nonspecific feature of many infections Mild viral hepatitis
High transferases, elevated bilirubin	Viral hepatitis (usually A, B or E)
Coagulation	May be deranged in hepatitis and in overwhelming infection of any type

Direct tests

Some microbiological tests rely on direct examination of a tissue specimen (e.g. blood, CSF or urine) for the presence of microorganisms. Microscopy and electron microscopy fall into this category. Other direct tests identify specific microbial components such as nucleic acids, cell wall molecules and other antigens. Specific genes from many pathogenic microorganisms have been cloned and sequenced.

Nucleic acid detection

Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The use of nucleic acid amplification techniques (NAAT) such as the polymerase chain reaction (PCR) has increased the power of these tests to detect very small quantities of microbial material. Such techniques are not only exquisitely sensitive, but may also enable quantitation, e.g. viral load testing and sub-speciation, e.g. at the genotype level. However, the ability to detect tiny amounts of nucleic acid in a sample means that there is a significant potential for false-positive results due to contamination. This is less likely when looking for viral nucleic acid and it is in the area of virology that NAAT tests are most widely used. A recent development for bacterial identification is the introduction to clinical practice of PCR tools for amplifying bacterial ribosome 16S subunits. This allows 'screening' of clinical samples for a wide range of organisms, but because of the risk of contamination results must be interpreted carefully in the light of clinical findings.

Culture

Another way of 'amplifying' the yield of microorganisms to a detectable level is through culture. Culture techniques can be applied to a wide variety of bacteria, fungi and viruses. However, some organisms are difficult to grow and may require special culture media and conditions. Viruses are particularly difficult (and in many cases impossible) to culture in the laboratory.

Specimens to be sent for microscopy and culture (Box 4.3):

- **Blood and urine** should routinely be sent for bacterial culture if infection is suspected, regardless of whether fever is present at the time.
- **Cerebrospinal fluid, sputum and biopsy** specimens are sent if clinically indicated.
- **Special culture techniques** are required for fungi, mycobacteria and some other bacteria such as *Brucella* spp., and the laboratory must be informed if these are suspected.
- **Faecal culture** for viruses is not helpful in the investigation of gastroenteritis – the viruses responsible for this do not grow in routine tissue culture. Antigen or nucleic acid detection techniques (see below) are more appropriate, especially in the investigation of an outbreak of diarrhoea and vomiting. Protozoa should be considered as a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers, men having sex with men, farm workers and in any cases of prolonged unexplained diarrhoea. Detection of a specific clostridial toxin is a more reliable test for diarrhoea caused by *Clostridium difficile* than culture of the organism itself. Stool culture is a costly routine test and is often requested unnecessarily.

Box 4.3 Specimens and indications for microscopy, culture and other microbiological tests

Specimen	Investigation	Indication
Blood	Giemsa stain for malaria Malaria antigen detection test Stains for other parasites Culture	Any symptomatic traveller returning from a malarious area Specific tropical infections All suspected bacterial infections
Urine	Microscopy and culture Tuberculosis (TB) culture NAAT	All suspected bacterial infections Suspected TB Unexplained leucocytes in urine STIs
Faeces	Microscopy ± iodine stain Culture PCR/antigen detection (not usually necessary to do both) <i>Clostridium difficile</i> toxin	Suspected protozoal diarrhoea All unexplained diarrhoea Suspected viral diarrhoea in children Diarrhoea following hospital stay or antibiotic treatment
Throat swabs	Culture PCR PCR/antigen detection	Suspected bacterial tonsillitis and pharyngitis Viral meningitis Viral respiratory infections where urgent diagnosis is considered necessary
Sputum	Microscopy and culture Auramine stain/TB culture (liquid culture, see p. 120) Other special stains/cultures	Unusual chest infections; pneumonia Suspected TB Immunocompromised patients Suspected fungal infections
Cerebrospinal fluid	Microscopy and culture Auramine stain/TB culture Other special stains/cultures PCR	Suspected meningitis Suspected TB, meningitis Immunocompromised patients Suspected fungal infections Suspected encephalitis or viral or bacterial meningitis
Rash aspirate: Petechial Vesicular	Microscopy and culture PCR/antigen detection/viral culture	Meningococcal disease Herpes simplex/zoster

NAAT, nuclear acid amplification test; PCR, polymerase chain reaction; STI, sexually transmitted infection.

Immunodiagnostic tests

These can be divided into two types:

- Tests that detect microbial components, using a polyvalent antiserum or a monoclonal antibody
- Tests that detect an antibody response to infection (serological tests).

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses and fungi, and can also be helpful when antibiotics have been administered before samples were obtained. However, care is needed in the interpretation of serological tests. Elevated antibody titres on a single occasion (especially of IgG) are rarely diagnostic and in some infections it may be difficult to distinguish between past and acute infection. Paired serological tests a few weeks apart, or specific assays for IgM antibodies (indicating an acute infection), are more helpful. Avidity testing may also enable distinction between recent (low avidity antibodies) and historical (high avidity) infection. Numerous serological tests are available: they should only be used in the light of the clinical picture and not as a general 'trawl' for a diagnosis.

Treatment

Many infections, particularly those caused by viruses, are self-limiting and require no treatment. The mainstay of therapy for most infectious diseases that do require treatment is antimicrobial chemotherapy. The choice of antibiotic should be governed by:

- The clinical state of the patient
- The likely cause of the infection.

Serious infections may require supportive therapy in addition to antibiotics. It is always preferable to have a definite microbial diagnosis before starting treatment, so that an antibiotic with the most appropriate spectrum of activity and site of action can be used. However, some patients are too unwell to wait for results (which in the case of culture may take days). In diseases such as meningitis or septicaemia delay in treatment may be fatal and therapy must be started on an empirical basis. Appropriate samples for culture should be taken before the first dose of antibiotic and an antibiotic regimen chosen on the basis of the most likely causative organisms. Usually patients are less unwell and specific therapy can be deferred pending results. (Antibiotic therapy is discussed in more detail on [page 85](#).)

Special circumstances

Returning travellers. A detailed travel itinerary, including any flight stopovers, should be taken from anyone who is unwell after arriving from another country. Previous travel should also be covered as some infections may be chronic or recurrent. It is necessary to find out not just which countries were visited but also the type of environment: a stay in a remote jungle village carries different health risks from a holiday in an air-conditioned coastal holiday resort. Food and water consumption, bathing and swimming habits, animal and insect contact and contact with human illness all need to be established. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral) while abroad. In some parts of the world, over 90% of professional sex workers are HIV-positive and hepatitis B and C are very common in parts of Africa and Asia. In addition to the investigations described in the previous section, special tests may be needed depending on the

epidemiological risks and clinical signs and malaria films are mandatory in anyone who is unwell after being in a malarious area. Some of the more common causes of a febrile illness in returning travellers are listed in Table 4.8.

Immunocompromised patients. Advances in medical treatment over the past three decades have led to a huge increase in the number of patients living with immunodeficiency states. Cancer chemotherapy, the use of immunosuppressive drugs and the worldwide AIDS epidemic have all contributed to this. The presentation may be very atypical in the immunocompromised patient with few, if any, localizing signs or symptoms. Infection can be due to organisms which are not usually pathogenic, including environmental bacteria and fungi. The normal physiological responses to infection (e.g. fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden and the course of the illness fulminant. A high index of suspicion for infections in people who are known to be immunosuppressed is required.

Table 4.8 Causes of febrile illness in travellers returning from the tropics and worldwide

<i>WHO advises that fever occurring in a traveller 1 week or more after entering a malaria risk area and up to 3 months after departure is a medical emergency</i>	
Developing countries	Specific geographical areas (see text)
Malaria	Histoplasmosis
Schistosomiasis	Brucellosis
Dengue	Worldwide
Tick typhus	Influenza
Typhoid	Pneumonia
Tuberculosis	URTI
Dysentery	UTI
Hepatitis A	Traveller's diarrhoea
Amoebiasis	Viral infection
URTI, upper respiratory tract infection; UTI, urinary tract infection.	

These patients may need early and aggressive antibiotic therapy without waiting for the results of investigations. Samples for culture should be sent before starting treatment, but therapy should not be delayed if this proves difficult. The choice of antibiotics should be guided by the likely causative organisms: these are shown in Box 4.4.

Injecting drug users. Parenteral drug use is associated with a variety of local and systemic infections. HIV, HBV and HCV can all be transmitted by sharing injecting equipment. Abscesses and soft tissue infections at the site of injection are common, especially in the groin, and may involve adjacent vascular and bony structures. Systemic infections are also common, most frequently caused by staphylococci and group A streptococci, but a wide variety of other bacterial and fungal pathogens may be implicated.

Highly transmissible infections. Relatively few patients with infectious disease present a serious risk to healthcare workers (HCW) and other contacts. However, the appearance of diseases like the 'new' strains of influenza (such as H5N1 avian influenza and pandemic H1N1), the occasional importation of zoonoses like Lassa fever and concerns about the bioterrorist use of agents such as smallpox mean that there is still the potential for unexpected outbreaks of life-threatening disease. During the worldwide SARS outbreak in 2003, scrupulous infection control procedures reduced spread of infection. However, in the 'inter-epidemic' period it is difficult to maintain the same level of alert. HCWs should remain vigilant because the early symptoms of many of these diseases are nonspecific. Many HCWs are developing multi-resistant TB from HIV patients with resistant TB organisms, which is becoming a very significant problem in Africa.

Pyrexia of unknown origin

History, clinical examination and simple investigation will reveal the cause of a fever in most patients. In a small number, however, no diagnosis is apparent despite continuing symptoms. The term pyrexia (or fever) of unknown origin

Box 4.4 Common causes of infection in immunocompromised patients

Deficiency	Causes	Organisms
Neutropenia	Chemotherapy Myeloablative therapy Immunosuppressant drugs	<i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Staph. aureus</i> <i>Staph. epidermidis</i> <i>Aspergillus</i> spp. <i>Candida</i> spp.
Cellular immune defects	HIV infection Lymphoma Myeloablative therapy Congenital syndromes	Respiratory syncytial virus Cytomegalovirus Epstein-Barr virus Herpes simplex and zoster <i>Salmonella</i> spp. <i>Mycobacterium</i> spp. (esp. <i>M. avium-intracellulare</i>) <i>Cryptococcus neoformans</i> <i>Candida</i> spp. <i>Cryptosporidium parvum</i> <i>Pneumocystis jiroveci</i> <i>Toxoplasma gondii</i>
Humoral immune deficiencies	Congenital syndromes Chronic lymphocytic leukaemia Corticosteroids	<i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> Enteroviruses
Terminal complement deficiencies (C5–C9)	Congenital syndromes	<i>Neisseria meningitidis</i> <i>N. gonorrhoeae</i>
Splenectomy	Surgery Trauma	<i>Strep. pneumoniae</i> <i>N. meningitidis</i> <i>H. influenzae</i> Malaria

Box 4.5 Causes of pyrexia of unknown origin

Infection (20–40%)

- Pyogenic abscess
- Tuberculosis
- Infective endocarditis
- Toxoplasmosis
- Epstein–Barr virus (EBV) infection
- Cytomegalovirus (CMV) infection
- Primary HIV infection
- Brucellosis
- Lyme disease

Malignant disease (10–30%)

- Lymphoma
- Leukaemia
- Renal cell carcinoma
- Hepatocellular carcinoma

Vasculitides (15–20%)

- Adult Still's disease
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Wegener's granulomatosis
- Giant cell arteritis
- Polymyalgia rheumatica

Miscellaneous (10–25%)

- Drug fevers
- Thyrotoxicosis
- Inflammatory bowel disease
- Sarcoidosis
- Granulomatous hepatitis
- Factitious fever
- Familial Mediterranean fever

Undiagnosed (5–25%)

(PUO) is sometimes used to describe this problem. Various definitions have been suggested for PUO: a useful one is 'a fever persisting for >2 weeks, with no clear diagnosis despite intelligent and intensive investigation'. Patients who are known to have HIV or other immunosuppressing conditions are normally excluded from the definition of PUO, as the investigation and management of these patients is different.

Successful diagnosis of the cause of PUO depends on knowledge of the likely and possible aetiologies. These have been documented in a number of studies and are summarized in Box 4.5.

A detailed history and examination is essential, taking into account the possible causes, and the examination should be repeated on a regular basis in case new signs appear. Investigation findings to date should be reviewed, obvious omissions amended and abnormalities followed up. Confirm that the patient does have objective evidence of a raised temperature: this may require admission to hospital if the patient is not already under observation. Some people have an exaggerated circadian temperature variation (usually peaking in the evening), which is not pathological.

The range of tests available is discussed above. Obviously investigation is guided by particular abnormalities on examination or initial test results, but in some cases 'blind' investigation is necessary. Some investigations, especially cultures, should be repeated regularly and serial monitoring of inflammatory markers such as C-reactive protein allows assessment of progress.

Improvements in imaging techniques have diminished the need for invasive investigations in PUO and scanning has superseded the blind diagnostic laparotomy. Ultrasound, echocardiography, CT, MRI, PET and labelled white cell scanning can all help in establishing a diagnosis if used appropriately: the temptation to scan all patients with PUO

from head to toe as a first measure should be avoided. Biopsy of bone marrow (and less frequently liver) may be useful even in the absence of obvious abnormalities and temporal artery biopsy should be considered in the elderly (see p. 543). Bronchoscopy can be used to obtain samples for microbiological and histological examination if sputum specimens are not adequate. Molecular and serological tests have greatly improved the diagnosis of infectious causes of PUO, but these tests should only be ordered and interpreted in the context of the clinical findings and epidemiology.

Treatment of a patient with a persistent fever is aimed at the underlying cause and if possible only symptomatic treatment should be used until a diagnosis is made. Blind antibiotic therapy may make diagnosis of an occult infection more difficult and empirical steroid therapy may mask an inflammatory response without treating the underlying cause. In a few patients no cause for the fever is found despite many months of investigation and follow-up. In most of these the symptoms do eventually settle spontaneously and if no definite cause has been identified after 2 years, the long-term prognosis is good.

ANTIMICROBIAL CHEMOTHERAPY

Principles of use

Antibiotics are among the safest of drugs, especially those used to treat community infections. They have had a major impact on the life-threatening infections and reduce the morbidity associated with surgery and many common infectious diseases. This in turn is, in part, responsible for the overprescribing of these agents which has led to concerns with regard to the increasing incidence of antibiotic resistance.

Empirical 'blind' therapy

Most antibiotic prescribing, especially in the community, is empirical. Even in hospital practice, microbiological documentation of the nature of an infection and the susceptibility of the pathogen is generally not available for a day or two. Initial choice of therapy relies on a clinical diagnosis and, in turn, a presumptive microbiological diagnosis. Such 'blind therapy' is directed at the most likely pathogen(s) responsible for a particular syndrome such as meningitis, urinary tract infection, or pneumonia. Examples of 'blind therapy' for these three conditions are ceftriaxone, trimethoprim and amoxicillin (\pm macrolide), respectively. Initial therapy in the severely ill patient is often broad spectrum in order to cover the range of possible pathogens but should be targeted once microbiological information becomes available. In patients with less severe infections a narrower-spectrum agent can be used from the outset while awaiting culture results, as the potential consequences of initial inadequate coverage are less serious.

Combination therapy

Combinations of drugs are occasionally required for reasons other than providing broad-spectrum cover. Tuberculosis is initially treated with three or four agents to avoid resistance emerging. Synergistic inhibition is achieved by using penicillin and gentamicin in enterococcal endocarditis or gentamicin and ceftazidime in life-threatening pseudomonas infection.

In the majority of infections, there is no firm evidence that bactericidal drugs (penicillins, cephalosporins, aminoglycosides) are more effective than bacteriostatic drugs

(tetracyclines), but it is generally considered better to use the former in the treatment of bacterial endocarditis and in patients in whom host defence mechanisms are compromised, particularly in those with neutropenia.

Pharmacokinetic factors

To be successful, sufficient antibiotic must penetrate to the site of the infection. Knowledge of the standard pharmacokinetic considerations of absorption, distribution, metabolism and excretion for the various drugs is required. Difficult sites include the brain, eye and prostate, while loculated abscesses are inaccessible to most agents.

Many mild-to-moderate infections can be treated effectively with oral antibiotics provided that the patient is compliant. Parenteral administration is indicated in the severely ill patient to ensure rapid high and/or consistent blood and tissue concentrations of drug. Some antibiotics can only be administered parenterally, such as the aminoglycosides and extended-spectrum cephalosporins. Parenteral therapy is also required in those unable to swallow or where gastrointestinal absorption is unreliable.

Dose and duration of therapy

This will vary according to the nature, severity and response to therapy. The need to completely clear the infection must be balanced against the undesired effects of prolonged antibiotic therapy (e.g. promotion of antimicrobial resistance, drug toxicity, superinfection with organisms such as *Candida* spp. or *Clostridium difficile* and cost). For many infections 5–7 days of treatment is adequate, while for some (e.g. uncomplicated urinary tract infections and some forms of bacterial gastroenteritis) 1–3 days may be enough. However, other infections may require much longer: bacterial endocarditis normally needs 4–6 weeks, bone and prosthetic joint infections often need 12 weeks and mycobacterial infections require months or even years of therapy. In a few conditions such as HIV or chronic hepatitis B infection treatment is suppressive rather than curative so lifelong antimicrobial treatment is needed. Even within a course of treatment it may be possible to simplify or streamline therapy, e.g. change from intravenous to oral or from broad spectrum to narrow spectrum, as the patient improves.

Renal and hepatic insufficiency

Patients with renal impairment may require reduction in dose or increased dosing interval in order to avoid toxic accumulation of antibiotic. This applies to the β -lactams and especially the aminoglycosides and vancomycin. In those with hepatic insufficiency, dose reduction is often required for agents which rely on extensive hepatic metabolism for excretion. A full list of such drugs can be found in the British National Formulary (BNF).

Therapeutic drug monitoring

To ensure therapeutic yet non-toxic drug concentrations, serum concentrations of drugs such as the aminoglycosides and vancomycin should be monitored, especially in those with impaired or changing renal function. Specific monitoring algorithms are available for such drugs (general guidance is provided in the BNF, but local guidelines should be followed wherever possible).

Antibiotic chemoprophylaxis

The value of antibiotic chemoprophylaxis has been questioned as there are few controlled trials to prove efficacy (see p. 708). The evidence for chemoprophylaxis against infective

endocarditis (IE) is an example. New English guidelines recognize that procedures can cause bacteraemia but without significant risk of infective endocarditis. Even patients at 'high risk', e.g. previous IE, prosthetic heart valves and surgical shunts, do not always require prophylaxis (Table 4.9). However, there are a number of indications for which the prophylactic use of antibiotics is still advised. These include surgical procedures where the risk of infection is high (colon surgery) or the consequences of infection are serious (post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen.

Mechanisms of action and resistance to antimicrobial agents

Antibiotics act at different sites of the bacterium, either inhibiting essential steps in metabolism or assembly or destroying vital components such as the cell wall.

Resistance to an antibiotic can be the result of:

- Impaired or altered permeability of the bacterial cell envelope, e.g. penicillins in Gram-negative bacteria
- Active expulsion from the cell by membrane efflux systems
- Alteration of the target site (e.g. single point mutations in *E. coli* or a penicillin-binding protein in *Strep. pneumoniae* leading to acquired resistance, see below)
- Overproduction of target site
- Specific enzymes which inactivate the drug before or after cell entry (e.g. β -lactamases)
- Development of a novel metabolic bypass pathway.

The development or acquisition of resistance to an antibiotic by bacteria involves either a mutation at a single point in a gene or transfer of genetic material from another organism (Fig. 4.4).

Larger fragments of DNA may be introduced into a bacterium either by transfer of 'naked' DNA or via a bacteriophage (a virus) DNA vector. Both the former (transformation) and the latter (transduction) are dependent on integration of this new DNA into the recipient chromosomal DNA. This requires a high degree of homology between the donor and recipient chromosomal DNA.

Finally, antibiotic resistance can be transferred from one bacterium to another by conjugation, when extrachromosomal DNA (a plasmid) containing the resistance factor (R factor) is passed from one cell into another during direct contact. Transfer of such R factor plasmids can occur between unrelated bacterial strains and involve large amounts of DNA and often codes for multiple antibiotic resistance, e.g. as for the quinolones.

Transformation is probably the least clinically relevant mechanism, whereas transduction and R factor transfer are usually responsible for the sudden emergence of multiple antibiotic resistance in a single bacterium. Increasing resistance to many antibiotics has developed (Table 4.10).

Antibacterial drugs **β -Lactams (penicillins, cephalosporins and monobactams)****Penicillins**

Structure. The β -lactams share a common ring structure (Fig. 4.5). Changes to the side-chain of benzylpenicillin (penicillin G) render the phenoxymethyl derivative (penicillin V)

Table 4.9 Antibiotic chemoprophylaxis

(a) General		
Clinical problem	Aim	Drug regimen^a
Splenectomy/spleen malfunction	To prevent serious pneumococcal sepsis	Phenoxymethylpenicillin 500 mg 12-hourly
Rheumatic fever	To prevent recurrence and further cardiac damage	Phenoxymethylpenicillin 250 mg × 2 daily or sulfadiazine 1 g if allergic to penicillin
Meningitis:		
Due to meningococci	To prevent infection in close contacts	Adults: rifampicin 600 mg twice-daily for 2 days (Children <1 year: 5 mg/kg; >1 year: 10 mg/kg)
Due to <i>H. influenzae</i> type b	To reduce nasopharyngeal carriage and prevent infection in close contacts	Alternative (single dose) ciprofloxacin 500 mg (p.o.) or ceftriaxone 250 mg (i.m.) Adults: rifampicin 600 mg daily for 4 days (Children: <3 months 10 mg/kg; >3 months 20 mg/kg)
Tuberculosis	To prevent infection in exposed (close contacts) tuberculin-negative individuals, infants of infected mothers and immunosuppressed patients	Oral isoniazid 300 mg daily for 6 months (Children: 5–10 mg/kg daily)
(b) Endocarditis (NICE guidelines for adults and children undergoing interventional procedures March 2008)		
Antibacterial prophylaxis and chlorhexidine mouthwash are not recommended for the prevention of endocarditis in patients undergoing dental procedures.		
Antibacterial prophylaxis is not recommended for the prevention of endocarditis in patients undergoing procedures of the:		
Upper and lower respiratory tract (including ear, nose and throat procedures and bronchoscopy)		
Genitourinary tract (including urological, gynaecological and obstetric procedures)		
Upper and lower gastrointestinal tract.		
Any infection in patients at risk of endocarditis should be investigated promptly and treated appropriately to reduce the risk of endocarditis.		
If patients at risk of endocarditis are undergoing a gastrointestinal or genitourinary tract procedure at a site where infection is suspected, they should receive appropriate antibacterial therapy that includes cover against organisms that cause endocarditis.		
Patients at risk of endocarditis should be:		
Advised to maintain good oral hygiene		
Told how to recognize signs of infective endocarditis and advised when to seek expert advice.		
^a Unless stated, doses are those recommended in adults. For surgical procedure, see individual procedures in text.		
Adapted from Joint Formulary Committee <i>British National Formulary</i> , 63rd edn. London: BMJ Group and RPS Publishing; 2012.		

**Figure 4.4 Some mechanisms for the development of resistance to antimicrobial drugs.** These involve either a single point mutation or transfer of genetic material from another organism (transformation, transduction or R factor transfer).

acid resistant and allow it to be orally absorbed. The presence of an amino group in the phenyl radical of benzylpenicillin increases its antimicrobial spectrum to include many Gram-negative and Gram-positive organisms. More extensive modification of the side-chain (e.g. as in flucloxacillin) renders the drug insensitive to bacterial penicillinase. This is useful in treating infections caused by penicillinase (β -lactamase)-producing staphylococci.

Mechanisms of action. β -lactams block bacterial cell wall mucopeptide formation by binding to and inactivating specific penicillin-binding proteins (PBPs), which are peptidases involved in the final stages of cell wall assembly and division. Methicillin-resistant *Staph. aureus* (MRSA) (see p. 115) produce a low-affinity PBP which retains its peptidase activity even in the presence of high concentrations of methicillin. Many bacteria have developed the ability to produce penicillinases and

Table 4.10 Some bacteria that have developed resistance to common antibiotics

Pathogen	Previously fully sensitive to:
Enterobacteria	Amoxicillin, trimethoprim, ciprofloxacin, gentamicin, glycopeptide (GRE), vancomycin (VRE)
<i>Helicobacter pylori</i>	Metronidazole, clarithromycin
<i>Haemophilus influenzae</i>	Amoxicillin, chloramphenicol
<i>E. coli</i>	Quinolones
<i>Neisseria gonorrhoeae</i>	Penicillin, ciprofloxacin
<i>Pseudomonas aeruginosa</i>	Gentamicin
<i>Salmonella</i> spp.	Amoxicillin, sulphonamides, ciprofloxacin
<i>Shigella</i> spp.	Amoxicillin, trimethoprim, tetracycline
<i>Staphylococcus aureus</i>	Penicillin, meticillin (MRSA), vancomycin (VISA), ciprofloxacin
<i>Streptococcus pneumoniae</i>	Penicillin, erythromycin, cefotaxime
<i>Streptococcus pyogenes</i>	Erythromycin, tetracycline
<i>Vibrio cholerae</i>	Quinolones, azithromycin

**Figure 4.5** The structure of penicillins.

beta-lactamases, which inactivate antibiotics of this class. Recent years have seen the emergence of Gram-negative organisms producing extended-spectrum beta-lactamases (ESBLs), rendering the bacteria potentially resistant to all beta-lactam antibiotics.

Indications for use. Benzylpenicillin can only be given parenterally and is still the drug of choice for some serious infections. However due to increasing antimicrobial resistance it should not be used as monotherapy in serious infections without laboratory confirmation that the organism is penicillin sensitive. Uses include serious streptococcal infections (including infective endocarditis), necrotizing fasciitis and gas gangrene, actinomycosis, anthrax and spirochaetal infections (syphilis, yaws).

Phenoxymethylpenicillin (penicillin V) is an oral preparation that is used chiefly to treat streptococcal pharyngitis and as prophylaxis against rheumatic fever.

Flucloxacillin is used in infections caused by beta-lactamase (penicillinase)-producing staphylococci and remains the drug of choice for serious infections caused by meticillin-sensitive *S. aureus* (MSSA).

Cephalosporin**Figure 4.6** The structure of a cephalosporin.

Ampicillin is susceptible to beta-lactamase, but its antimicrobial activity includes streptococci, pneumococci and enterococci as well as Gram-negative organisms such as *Salmonella* spp., *Shigella* spp., *E. coli*, *H. influenzae* and *Proteus* spp. Drug resistance has, however, eroded its efficacy against these Gram-negatives. It is widely used in the treatment of respiratory tract infections. Amoxicillin has similar activity to ampicillin, but is better absorbed when given by mouth.

The extended-spectrum penicillin, ticarcillin, is active against pseudomonas infections, as is the acylureidopenicillin piperacillin in combination with sulbactam.

Clavulanic acid is a powerful inhibitor of many bacterial beta-lactamases and when given in combination with an otherwise effective agent such as amoxicillin (co-amoxiclav) or ticarcillin can broaden the spectrum of activity of the drug. Sulbactam acts similarly and is available combined with ampicillin, while tazobactam in combination with piperacillin is effective in appendicitis, peritonitis, pelvic inflammatory disease and complicated skin infections. The penicillin beta-lactamase combinations are also active against beta-lactamase-producing staphylococci.

Pivmecillinam has significant activity against Gram-negative bacteria including *E. coli*, *Klebsiella*, *Enterobacter* and *Salmonella* but not against *Pseudomonas*.

Temocillin is active against Gram-negative bacteria, including beta-lactamase producers. It is not active against *Pseudomonas* or *Acinetobacter* spp.

Interactions. Penicillins inactivate aminoglycosides when mixed in the same solution.

Toxicity. Generally, the penicillins are very safe. Hypersensitivity (skin rash (common), urticaria, anaphylaxis), encephalopathy and tubulointerstitial nephritis can occur. Ampicillin also produces a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis who receive this drug. Co-amoxiclav causes a cholestatic jaundice six times more frequently than amoxicillin, as does flucloxacillin.

Cephalosporins

The cephalosporins (Fig. 4.6) have an advantage over the penicillins in that they are resistant to staphylococcal penicillinases (but are still inactive against meticillin-resistant staphylococci) and have a broader range of activity that includes both Gram-negative and Gram-positive organisms, but excludes enterococci and anaerobic bacteria. Cefazidime and cefepime are active against *Pseudomonas aeruginosa*.

Indications for use (Table 4.11). These potent broad-spectrum antibiotics are useful for the treatment of serious systemic infections, particularly when the precise nature of the infection is unknown. They may be used for serious sepsis in postoperative and immunocompromised patients, as well as for meningitis and intra-abdominal sepsis, but are increasingly being replaced by other agents because of their link with *Clostridium difficile* associated diarrhea (CDAD).

Interactions. There are relatively few interactions.

Table 4.11 Some examples of cephalosporins

	Activity	Use
First generation Cefalexin (oral) Cefradine (oral) Cefadroxil (oral)	Gram-positive cocci and Gram-negative organisms	Urinary tract infections Penicillin allergy
Second generation Cefuroxime Cefamandole ^a Cefoxitin ^a Cefaclor (oral) Cefuroxime (oral) Cefprozil (oral) ^a	Extended spectrum More effective than first generation against <i>E. coli</i> , <i>Klebsiella</i> spp. and <i>Proteus mirabilis</i> , but less effective against Gram-positive organisms Includes <i>Bacteroides fragilis</i>	Prophylaxis and treatment of Gram-negative infections and mixed aerobic-anaerobic infections Peritonitis
Third generation Cefotaxime Ceftazidime Cefpirome ^a Ceftriaxone Cefpodoxime (oral) Cefixime (oral)	Broad-spectrum More potent against aerobic Gram-negative bacteria than first or second generation	Especially severe infection with Enterobacteriaceae, <i>Pseudomonas aeruginosa</i> (ceftazidime, cefpirome) and <i>Neisseria gonorrhoeae</i> , <i>N. meningitidis</i> , Lyme disease (ceftriaxone) Urinary tract infections and infections with neutropenia Once daily. Septicaemia, pneumonia, meningitis
Fourth generation Cefepime ^a	Aerobic Gram-negative bacteria including <i>P. aeruginosa</i>	Febrile, neutropenic patients
Fifth generation Ceftaroline ^a Ceftobiprole ^a	Similar to third generation but active against MRSA	Not yet in widespread use

^aUnavailable in the UK.

Toxicity. The toxicity is similar to that of the penicillins but is less common. Some 10% of patients are allergic to both groups of drugs. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects. Second and third generation cephalosporins are strongly associated with CDAD and alternative antibiotics should be used when possible.

Monobactams

Aztreonam is currently the only member of this class available. It is a synthetic β -lactam and, unlike the penicillins and cephalosporins, has no ring other than the β -lactam, hence its description as a monobactam.

Its mechanism of action is by inhibition of bacterial cell wall synthesis. It is resistant to most β -lactamases and does not induce β -lactamase production.

Indications for use. Aztreonam's spectrum of activity is limited to aerobic Gram-negative bacilli. It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis, and is also used in pseudomonas infection (including lung infection in cystic fibrosis).

Toxicity. As for the β -lactam antibiotics.

Carbapenems

The carbapenems are semisynthetic β -lactams and include imipenem, meropenem, doripenem and ertapenem. They are currently the broadest spectrum of antibiotics, being active against the majority of Gram-positive and Gram-negative as well as anaerobic bacterial pathogens. Ertapenem, unlike the others, is not active against *Pseudomonas* or *Acinetobacter* spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by

**Figure 4.7** The structure of an aminoglycoside.

enzymatic inactivation and is therefore administered in combination with cilastatin.

Indications for use. They are used for serious nosocomial infections when multiple-resistant Gram-negative bacilli or mixed aerobe and anaerobe infections are suspected.

Toxicity. This is similar to that of β -lactam antibiotics. Nausea, vomiting and diarrhoea occur in less than 5% of cases. Imipenem may cause seizures and should not be used to treat meningitis; meropenem is safe for this indication.

Aminoglycosides

Structure. These antibiotics are polycationic compounds of amino sugars (Fig. 4.7).

Mechanism of action. Aminoglycosides interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger and transfer RNA).

Indications for use. Streptomycin is bactericidal and is rarely used except for the treatment of tularaemia or plague. Neomycin is used only for the topical treatment of eye and skin infections. Even though it is poorly absorbed, prolonged oral administration can produce ototoxicity.

Gentamicin and tobramycin are given parenterally. They are highly effective against many Gram-negative organisms including *Pseudomonas* spp. They are synergistic with a penicillin against *Enterococcus* spp. Netilmicin and amikacin have a similar spectrum but are more resistant to the aminoglycoside-inactivating enzymes (phosphorylating, adenylating or acetylating) produced by some bacteria. Their use should be restricted to gentamicin-resistant organisms.

Interactions. Enhanced nephrotoxicity occurs with other nephrotoxic drugs, ototoxicity with some diuretics and neuromuscular blockade with curariform drugs.

Toxicity. This is dose-related. Aminoglycosides are nephrotoxic and ototoxic (vestibular and auditory), particularly in the elderly. Therapeutic drug monitoring is necessary in ensuring therapeutic and non-toxic drug concentrations.

Tetracyclines and glycylcyclines

Structure. These are bacteriostatic drugs possessing a four-ring hydronaphthacene nucleus (Fig. 4.8). Included among the tetracyclines are tetracycline, oxytetracycline, demeclocycline, lymecycline, doxycycline and minocycline. Tigecycline is an injectable glycylcycline, which is structurally related to the tetracyclines.

Mechanism of action. Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA).

Indications for use. Tetracyclines are active against Gram-positive and Gram-negative bacteria but their use is limited, partly owing to increasing bacterial resistance. Tetracyclines are active against *V. cholerae*, *Rickettsia* spp., *Mycoplasma* spp., *Coxiella burnetii*, *Chlamydia* spp. and *Brucella* spp.

Tigecycline, the only currently available glycylcycline, is active against many organisms resistant to tetracycline and other antibiotics. This includes vancomycin-resistant enterococci, MRSA and multidrug-resistant Gram-negative bacilli including *Acinetobacter* spp. Its indications include complicated skin and soft tissue infections and intra-abdominal sepsis. However a recent FDA alert has raised concern about the efficacy of tigecycline in some serious infections (notably ventilator-associated pneumonia, VAP) and it should be used only on expert advice.

Interactions. The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

Toxicity. Tetracyclines are generally safe drugs, but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group. They cause brown discoloration of growing teeth and thus these drugs are not given to children or pregnant women. Photosensitivity can occur. Nausea and vomiting are the most frequent adverse effects of tigecycline.

Figure 4.8 The structure of a tetracycline. Substitution of CH₃, OH or H at positions A–D produces variants of tetracycline.

Macrolides

Erythromycin and clarithromycin

Structure. Erythromycin and clarithromycin both consist of a lactone ring with two sugar side-chains, one of which is an aminosugar.

Mechanism of action. Macrolides inhibit protein synthesis by interrupting ribosomal function.

Indications for use. Erythromycin has a similar (but not identical) antibacterial spectrum to penicillin and may be useful in individuals with penicillin allergy, especially in the management of bacterial respiratory infections. It can be given orally or parenterally, but oral intake is associated with significant gastrointestinal side-effects, while the i.v. formulation is very irritant and causes phlebitis. For these reasons, clarithromycin (which has similar antimicrobial properties but fewer side-effects) is often preferred. These drugs are the preferred agent in the treatment of pneumonias caused by *Legionella* spp. and *Mycoplasma* spp. They are also effective in the treatment of infections due to *Bordetella pertussis* (whooping cough), *Campylobacter* spp. and *Chlamydia* spp.

Other macrolides

These include azithromycin and telithromycin. They have a broad spectrum of activity that includes selective Gram-negative organisms, mycobacteria and *Toxoplasma gondii*. Compared with erythromycin, they have superior pharmacokinetic properties with enhanced tissue and intracellular penetration and longer half-life that allows once daily dosage. Azithromycin is also used for trachoma and cholera (see p. 136). Fidaxomicin is useful in *C. difficile*.

Interactions. Erythromycin and other macrolides interact with theophyllines, carbamazepine, digoxin and ciclosporin, occasionally necessitating dose adjustment of these agents.

Toxicity. Diarrhoea, vomiting and abdominal pain are the main side-effects of erythromycin (less with clarithromycin and azithromycin) and are, in part, a consequence of the intestinal prokinetic properties of the macrolides. Macrolides may also rarely produce cholestatic jaundice after prolonged treatment. QT_c prolongation is a recognized cardiac effect of the macrolides. This may have serious consequences if the syndrome of 'torsades de pointes' is induced.

Chloramphenicol

Structure. Chloramphenicol is the only naturally occurring antibiotic containing nitrobenzene (Fig. 4.9). This structure probably accounts for its toxicity in humans and for its activity against bacteria.

Mechanism of action. Chloramphenicol competes with messenger RNA for ribosomal binding. It also inhibits peptidyl transferase.

Figure 4.9 The structure of chloramphenicol.

Indications for use. Chloramphenicol is now little used in developed countries, although it remains an effective and useful antibiotic in some situations. In developing countries, it has been invaluable in the treatment of meningitis and severe infections caused by *Salmonella typhi* and *S. paratyphi* (enteric fevers) and is also active against *H. influenzae* (meningitis and acute epiglottitis) and *Yersinia pestis* (plague). It is used topically for the treatment of purulent conjunctivitis. Drug resistance is currently eroding the efficacy of chloramphenicol.

Interactions. Chloramphenicol enhances the activity of anticoagulants, phenytoin and some oral hypoglycaemic agents.

Toxicity. Severe irreversible bone marrow suppression is rare but nevertheless now restricts the usage of this drug where alternatives exist. Chloramphenicol should not be given to premature infants or neonates because of their inability to conjugate and excrete this drug; high blood levels lead to circulatory collapse and the often fatal 'grey baby syndrome'.

Sodium fusidate

Structure. Sodium fusidate has a structure resembling that of bile salts (see p. 78).

Mechanism of action. It is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure.

Indications for use. Sodium fusidate is mainly used for penicillinase-producing *Staph. aureus* infections such as osteomyelitis (it is well concentrated in bone) or endocarditis and for other staphylococcal infections accompanied by septicaemia. The drug is well absorbed orally (i.v. preparations are also available) but is relatively expensive and should be used in combination with another staphylococcal agent to prevent resistance emerging.

Resistance. Resistance may occur rapidly and is the reason why sodium fusidate is given in combination with another antibiotic.

Toxicity. Sodium fusidate may occasionally be hepatotoxic but is generally a safe drug and if necessary can be given during pregnancy.

Sulphonamides and trimethoprim

Structure. The sulphonamides are all derivatives of the prototype sulphanilamide. Trimethoprim is a 2,4-diaminopyrimidine.

Mechanism of action. Sulphonamides block thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (see Fig. 8.12).

Indications for use. Sulfamethoxazole is mainly used in combination with trimethoprim (as co-trimoxazole). Its use is now largely restricted to the treatment and prevention of *Pneumocystis jiroveci* infection and listeriosis in developed countries, although it is still in widespread use in developing countries. It may also be used for toxoplasmosis and nocardiosis and as a second-line agent in acute exacerbations of chronic bronchitis and in urinary tract infections. Trimethoprim alone is often used for urinary tract infections and acute-on-chronic bronchitis, as the side-effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulfapyridine in combination with 5-aminosalicylic acid (i.e. sulfasalazine) is now less widely used in inflammatory bowel disease.

Resistance. Resistance to sulphonamides is often plasmid-mediated and results from the production of

Figure 4.10 The structure of a quinolone (ciprofloxacin).

sulphonamide-resistant dihydropteroate synthase from altered bacterial cell permeability to these agents.

Interactions. Sulphonamides potentiate oral anticoagulants and some hypoglycaemic agents.

Toxicity. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens–Johnson syndrome, thrombocytopenia, folate deficiency and megaloblastic anaemia with prolonged usage. It can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people.

Quinolones

The quinolone antibiotics, such as ciprofloxacin, norfloxacin, ofloxacin and levofloxacin, are useful oral broad-spectrum antibiotics, related structurally to nalidixic acid. The latter achieves only low serum concentrations after oral administration and its use is limited to the urinary tract where it is concentrated. Newer quinolones, including moxifloxacin, gemifloxacin and gatifloxacin, have greater activity against Gram-positive pathogens. The structure is shown in Figure 4.10.

Mechanism of action. The quinolone group of bactericidal drugs inhibits bacterial DNA synthesis by inhibiting topoisomerase IV and DNA gyrase, the enzyme responsible for maintaining the superhelical twists in DNA.

Indications for use. The extended-spectrum quinolones such as ciprofloxacin have activity against Gram-negative bacteria, including some *Pseudomonas aeruginosa* and some Gram-positive bacteria (e.g. anthrax, p. 132). They are useful in Gram-negative septicaemia, skin and bone infections, urinary and respiratory tract infections, meningococcal carriage, in some sexually transmitted diseases such as gonorrhoea and nonspecific urethritis due to *Chlamydia trachomatis* and in severe cases of travellers' diarrhoea (see p. 122). The newer oral quinolones provide an alternative to β -lactams in the treatment of community-acquired lower respiratory tract infections.

Resistance. In many countries 30–40% of *E. coli* are resistant. Resistance is also a growing problem among *Salmonella*, *Vibrio cholerae* and *Staphylococcus aureus*, including MRSA strains.

Interactions. Ciprofloxacin can induce toxic concentrations of theophylline.

Toxicity. Gastrointestinal disturbances, photosensitive rashes and occasional neurotoxicity can occur. Avoid in childhood and pregnancy and in patients taking corticosteroids. Tendon damage, including rupture, can occur within 48 h of use and the drug should be stopped immediately; it should not be used in patients with tendonitis. MRSA and *Clostridium difficile* infection in hospitals have been linked to

Falagas ME, Manta KG, Ntziora F et al. Linezolid for the treatment of patients with endocarditis: a systematic review of the published evidence. *J Antimicrob Chemother* 2006; 58: 273–280.

Figure 4.11 The structure of linezolid, an oxazolidinone.

high prescribing rates of quinolones and use is now discouraged where an effective alternative is available.

Oxazolidinones

Structure. The oxazolidinones are a novel class of antibacterial agents, of which linezolid (Fig. 4.11) is the first to be available.

Mechanism of action. The oxazolidinones inhibit protein synthesis by binding to the bacterial 23S ribosomal RNA of the 50S subunit, thereby preventing the formation of a functional 70S complex essential to bacterial translation.

Indications for use. Linezolid is active against a variety of Gram-positive pathogens including vancomycin-resistant *Enterococcus faecium* (although unfortunately resistant organisms have already been reported), methicillin-resistant *Staph. aureus* and penicillin-resistant *Strep. pneumoniae*. It is also active against group A and group B streptococci. Clinical experience has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, such as bacteraemia, hospital-acquired pneumonia and skin and soft tissue infections. It can be given both intravenously and by mouth.

Interactions. Linezolid interacts reversibly as a non-selective inhibitor of monoamine oxidase and has the potential for interacting with serotonergic and adrenergic agents.

Toxicity. Side-effects include gastrointestinal disturbances, headache, rash, hypertension, reversible but potentially severe cytopenias and occasional reports of optic neuropathy. Safety has not yet been shown in pregnancy.

Nitroimidazoles

Structure. These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is metronidazole. Others include tinidazole and nimorazole.

Mechanism of action. After reduction of their 'nitro' group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

Indications for use. Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to *Bacteroides* spp. It is also used prophylactically in colonic surgery. It may be given orally, by suppository (well absorbed and cheap) or intravenously (very expensive). It is also the treatment of choice for mild and moderate CDAD, amoebiasis, giardiasis and infection with *Trichomonas vaginalis*.

Interactions. Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin.

Toxicity. Nitroimidazoles are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste and polyneuropathy with prolonged use. They should be avoided in pregnancy.

Glycopeptides

The glycopeptides are antibiotics active against Gram-positive bacteria and act by inhibiting cell wall synthesis.

Vancomycin

Vancomycin is given intravenously for methicillin-resistant *Staph. aureus* and other multiresistant Gram-positive organisms. It is also used for treatment and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is used for *Strep. pneumoniae* meningitis when caused by penicillin-resistant strains. By mouth, it is an alternative to metronidazole for CDAD. Glycopeptide-resistant enterococci (GRE) are now seen, as well as vancomycin-resistant *Staphylococcus* (see p. 116).

Toxicity. Vancomycin can cause ototoxicity and nephrotoxicity and thus serum levels should be monitored. Care must be taken to avoid extravasation at the injection site as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

Teicoplanin

This glycopeptide antibiotic is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily dosage. It is given i.m. or i.v.

Other antibiotics

Clindamycin is not widely used because of its strong association with CDAD. It is active against Gram-positive cocci including some penicillin-resistant staphylococci and is a useful agent for severe streptococcal or staphylococcal cellulitis. It has the added effect of inhibiting staphylococcal TSST-1 and alpha toxin production and has a role in infections caused by *Staph. aureus* secreting Panton Valentine leucocidin (PVL). It is also active against anaerobes, especially bacteroides. It is well concentrated in bone and used for osteomyelitis.

Streptogramins. A combination of *quinupristin and dalfo-pristin* is used for Gram-positive bacteria which have failed to respond to other antibacterials. It has found only limited use and is not available in the UK. Virginiamycin and pristinamycin are also available.

Daptomycin is a lipopeptide with a similar spectrum to vancomycin and is given by i.v. infusion. It is particularly used for complicated skin and soft tissue infections including those caused by MRSA. It is also useful for endocarditis of the right heart there is increasing evidence of efficacy in other types of carditis and systemic infection.

Fosfomycin, which is a relatively old antibiotic and is not currently licensed in the UK, is effective against many Gram-negative bacteria. It retains activity against the majority of ESBL-producing organisms and is therefore the subject of renewed interest.

Antituberculosis drugs

These are described on page 842. Rifampicin is also used in other infections apart from tuberculosis.

Antifungal drugs (Table 4.12)

Polyenes

Polyenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is amphotericin, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem and dosage levels must take background renal function into account. Liposomal amphotericin is less toxic but very expensive. Nystatin is not absorbed through mucous

membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

Azoles

Imidazoles such as ketoconazole, miconazole and clotrimazole are broad-spectrum antifungal drugs. They are predominantly fungistatic and act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall. Ketoconazole is active orally but can produce liver damage. It is effective in candidiasis and deep mycoses including histoplasmosis and blastomycosis but not in aspergillosis and cryptococcosis.

Clotrimazole and miconazole are used topically for the treatment of ringworm and cutaneous and genital candidiasis. Econazole is used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections while tioconazole is indicated for fungal nail infections.

Triazoles. These include fluconazole, voriconazole and itraconazole. Fluconazole is noted for its ability to enter CSF and is used for candidiasis and for the treatment of central nervous system (CNS) infection with *Cryptococcus neoformans*. Itraconazole fails to penetrate CSF. It is the agent of choice for non-life-threatening blastomycosis and histoplasmosis. It is also moderately effective in invasive aspergillosis. Toxicity is mild. Voriconazole has broad-spectrum activity that includes *Candida*, *Cryptococcus* and *Aspergillus* spp. and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include rash, visual disturbance and abnormalities of liver enzymes. It is indicated for invasive aspergillosis and severe candida infections unresponsive to amphotericin and fluconazole, respectively.

Allylamines

Terbinafine has broad-spectrum antifungal and also anti-inflammatory activity. It is well absorbed orally and accumulates in keratin. It is useful for the treatment of superficial mycoses such as dermatophyte infections, onychomycosis and cutaneous candidiasis. A topical formulation is also available to treat fungal skin infections.

Echinocandins

These act by inhibiting the cell wall polysaccharide, glucan. Caspofungin, which is administered intravenously, is active against *Candida* spp. and *Aspergillus* spp. and is indicated for invasive candidiasis and invasive aspergillosis unresponsive to other drugs. Other echinocandins include micafungin

Palivizumab	Prevention in RSV
Protease inhibitors	
Telaprevir	Oral – HCV
Boceprevir	Oral – HCV

and anidulafungin, approved for the treatment of disseminated candidiasis.

Flucytosine

The fluorinated pyridine derivative, flucytosine, is used in combination with amphotericin B for cryptococcal meningitis. Side-effects are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally.

Antiviral drugs

Drugs for HIV infection are discussed on page 182.

Nucleoside analogues

Aciclovir. Aciclovir (also known as acycloguanosine) is an acyclic nucleoside analogue which acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by alpha herpesviruses, herpes simplex types 1 and 2 and varicella zoster virus (Table 4.13). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate acts as a potent inhibitor of viral (but not cellular) DNA polymerase and also competes with deoxyguanine triphosphate for incorporation into the growing chains of herpesvirus DNA, thereby resulting in chain synthesis termination due to its acyclic structure. This highly specific mode of activity, targeted only to virus-infected cells, means

a Aciclovir

b Cidofovir

The structure of antiviral drugs. (a) Aciclovir; (b) cidofovir.

that aciclovir has very low toxicity. Crystallization in the renal tubules is a well-recognized adverse effect. Intravenous, oral and topical preparations are available for the treatment of herpes simplex and varicella zoster virus infections (Table 4.13). Treatment does not eliminate the virus so relapses do occur.

Valaciclovir is an oral pro-drug of aciclovir. Coupling of the amino acid valine to the acyclic side-chain of aciclovir allows better intestinal absorption. The valine is removed by enzymic action and aciclovir is released into the circulation. A similar pro-drug of a related nucleoside analogue (penciclovir) is the antiherpes drug, famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.

Ganciclovir. This guanine analogue is structurally similar to aciclovir, with extension of the acyclic side-chain by a carboxymethyl group. It is active against herpes simplex viruses and varicella zoster virus by the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase encoded by the UL97 gene of cytomegalovirus renders it potentially active against this virus. Thus, ganciclovir is currently the first-line treatment for cytomegalovirus disease. Intravenous and oral preparations are available as is an oral pro-drug, valganciclovir. Unlike aciclovir, ganciclovir has a significant toxicity profile including neutropenia, thrombocytopenia and rarely, sterilization by inhibition of spermatogenesis. It is therefore reserved for the treatment or prevention of life- or sight-threatening cytomegalovirus infection in immunocompromised patients.

Lamivudine is a reverse transcriptase inhibitor active against both HIV and hepatitis B. Drug resistance is a problem (see pp. 81, 184).

Entecavir is a more potent inhibitor of hepatitis B and is active against lamivudine-resistant strains. *Telbivudine* and *emtricitabine* are also nucleoside analogue inhibitors of HBV DNA polymerase activity.

Nucleotide analogues

Cidofovir is a phosphonate derivative of an acyclic nucleoside which is a DNA polymerase chain inhibitor. It is administered intravenously for the treatment of severe cytomegalovirus (CMV) infections in patients with AIDS for whom other drugs are inappropriate. It is given with probenecid and as it is nephrotoxic, particular attention should be given to hydration and to monitoring renal function.

Adefovir dipivoxil has activity against hepatitis B virus DNA polymerase. However, *tenofovir disoproxil* is much more potent, has a much higher barrier to resistance and has therefore largely superseded adefovir in use (see p. 322).

Pyrophosphate analogues

Foscarnet (sodium phosphonoformate) is a simple pyrophosphate analogue which inhibits viral DNA polymerases. It is active against herpesviruses and its main roles are as a second-line treatment for severe cytomegalovirus disease and for the treatment of aciclovir-resistant herpes simplex infection. It is given intravenously and the potential for severe side-effects, particularly renal damage, limits its use.

Adamantanes

Amantadine. Amantadine (and its derivative rimantadine) is a synthetic symmetrical amine, which is active prophylactically and therapeutically against influenza A virus (it is inactive against influenza B virus). Its prophylactic efficacy is similar to that of influenza vaccine and it is occasionally used to prevent the spread of influenza A in institutions such as nursing homes. CNS side-effects such as insomnia,

dizziness and headache may occur (it is also used as a treatment for Parkinson's disease) and the drug is poorly tolerated, especially in the elderly.

Neuraminidase inhibitors

Zanamivir (administered by inhalation) and **oseltamivir** (an oral preparation) inhibit the action of the neuraminidase of influenza A and B. Both have been shown to be effective in reducing the duration of illness in influenza. Oseltamivir is also available for the prophylaxis of influenza among household contacts of an index case. Intravenous peramivir and zanamivir were both reported to be effective in treating patients during the 2010 influenza pandemic, but neither are currently licensed for routine use in this way.

Protease inhibitors

Two new protease inhibitors, **boceprevir** and **telaprevir**, have recently become available for treating chronic hepatitis C infection (in combination with ribavirin and interferon) (see p. 304).

Other drugs

Ribavirin. This synthetic purine nucleoside derivative which interferes with 5'-capping of messenger RNA, is active against several RNA and DNA viruses, at least *in vitro*. Its major use is in the treatment of chronic hepatitis C infection in combination with pegylated interferon- α , although it has no effect when given alone (see p. 324). It is administered orally. Haemolytic anaemia is the most frequent adverse reaction. It is also administered by a small-particle aerosol generator (SPAG) to infants with acute respiratory syncytial virus (RSV) infection. Another indication is in the treatment of Lassa fever virus infection.

Palivizumab. This monoclonal antibody is specifically indicated to prevent seasonal respiratory syncytial virus (RSV) infection in infants at high risk of this infection. It is administered by intramuscular injection.

Interferons

These are naturally occurring proteins with a multiplicity of actions, including antiviral, immunomodulatory and antiproliferative effects. Interferons are produced by virus-infected cells, macrophages and lymphocytes. They induce an antiviral state in uninfected cells, through activation of a complex set of biochemical pathways. They have been synthesized commercially by either culture of lymphoblastoid cells or by recombinant DNA technology and are licensed for therapeutic use.

The potency of INF- α has been enhanced by coupling the protein with polyethylene glycol. The resulting PEG interferon given once weekly has been shown to improve the response to, and reduce the side-effects from, treatment for hepatitis B and C.

IMMUNIZATION AGAINST INFECTIOUS DISEASES

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by:

- eliminating the source or mode of transmission of an infection (see p. 75);
- reducing host susceptibility to environmental pathogens.

Travellers to developing countries, especially if visiting rural areas, should in addition enquire about further specific immunizations.

In 1974, the World Health Organization introduced the Expanded Programme on Immunization (EPI). By 1994, more than 80% of the world's children had been immunized against tuberculosis, diphtheria, tetanus, pertussis, polio and measles. Poliomyelitis should shortly be eradicated worldwide, which will match the past success of global smallpox eradication. Introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib) has proved highly effective in controlling invasive *H. influenzae* infection, notably meningitis (see p. 1130).

Immunization e.g. tetanus, HBV, should be kept up to date in adults.

Protection for travellers to developing/tropical countries

There has been a huge increase in the number of people travelling to developing countries, mainly for recreation and

NHS Immunisation Information: <http://www.immunisation.nhs.uk>

The Green Book – Immunisation against Infectious Disease: [http://www.dh.gov.uk/en/PublicationsandStatistics/PublicationsPolicyAndGuidance/DH_079917](http://www.dh.gov.uk/en/PublicationsandStatistics/Publications/PublicationsPolicyAndGuidance/DH_079917)

Immunization, immunoprophylaxis and immunotherapy

Immunization has changed the course and natural history of many infectious diseases. Passive immunization by administering preformed antibody, either in the form of immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and treatment (immunotherapy) of a number of bacterial and viral diseases (Table 4.14). The active immunization schedule currently recommended is summarized in Box 4.6. Long-lasting immunity is achieved only by active immunization with a live attenuated or an inactivated organism or a subunit thereof (Table 4.15). Active immunization may also be performed with microbial toxin (either native or modified) – that is, a toxoid. Immunization should be kept up to date with booster doses throughout life.

National Travel
Health Network and
Centre: <http://www.nathnac.org>

leisure. The risk of infection depends on the area to be visited, the type of activity and the underlying health of the traveller. Advice should therefore always be based on an individual assessment.

Protection for travellers against infection can be divided into three categories:

- Personal protection, e.g.
 - insect repellents
 - impregnated bed netting

- avoidance of animals
- care with food and drink

- Chemoprophylaxis, e.g. antimalarials
- Immunization, e.g.
 - yellow fever
 - hepatitis A and B
 - typhoid.

Because situations and risks can change rapidly, websites (which can be regularly updated) are often the best source of advice on travel health.

VIRAL INFECTIONS

Introduction

Viruses are much smaller than other infectious agents (see Tables 4.16 and 4.18) and contain either DNA or RNA, not both as in bacteria and other microorganisms. Since they are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid core surrounded by a protein coat that is antigenically unique for a particular virus. The protein coat (capsid) imparts a helical or icosahedral structure to the virus. Some viruses also possess an outer envelope consisting of lipid and protein.

Outcomes of virus infection of a cell

Replication of viruses within a cell may result in sufficient distortion of normal cell function so as to result in cell death – a cytotoxic or cytolytic infection. However, acute cell death is not an inevitable consequence of virus infection of a cell. In a chronic, or persistent, infection, virus replication continues throughout the lifespan of the cell, but does not interfere with the normal cellular processes necessary for cell survival. Hepatitis B and C viruses may interact with cells in this way. Some viruses, e.g. the herpesvirus family, are able to go latent within a cell – in such a state, the virus genome is present within the cell, but there is very little, if any, produc-

tion of viral proteins and no production of mature virus particles. Finally, some viruses are able to transform cells, leading to uncontrolled cell division, e.g. Epstein–Barr virus infection of B lymphocytes, resulting in the generation of an immortal lymphoblastoid cell line.

DNA VIRUSES

Details of the structure, size and classification of human DNA viruses are shown in Table 4.16.

Adenoviruses

Over 50 adenovirus serotypes have been identified as human pathogens, infecting a number of different cell types and therefore resulting in different clinical syndromes. Adenovirus infection commonly presents as an acute pharyngitis and extension of infection to the larynx and trachea in infants may lead to croup. By school age the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and rarely pneumonia that is clinically similar to that produced by *Mycoplasma pneumoniae* (see p. 836). Certain

adenoviruses (40 and 41) cause gastroenteritis (see p. 104) without respiratory disease and adenovirus infection may be responsible for acute mesenteric lymphadenitis in children and young adults. Mesenteric adenitis due to adenoviruses may lead to intussusception in infants. Infection in an immunocompromised host, e.g. a bone marrow transplant recipient, may result in multisystem failure and fatal disease.

Herpesviruses

Members of the *Herpesviridae* family are causes of a wide range of human diseases. Details are summarized in Table 4.17. The hallmark of all herpesvirus infections is the ability of the viruses to establish latent (or silent) infections that then persist for the life of the individual.

Herpes simplex virus (HSV) infection

Two types of HSV (Fig. 4.12) have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis ('cold sore'), keratoconjunctivitis and encephalitis, whereas HSV-2 causes genital herpes and may also be responsible for systemic infection in the immunocompromised host. These divisions, however, are not rigid, for HSV-1 can give rise to genital herpes and HSV-2 can cause infections in the mouth.

HSV-1

The portal of entry of HSV-1 infection is usually via the mouth or occasionally the skin. The primary infection may go unnoticed or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; Fig. 4.13). The virus then remains latent, most commonly in the trigeminal ganglia, but may be reactivated by stress, trauma, febrile illnesses and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis ('cold sore'). Approximately 70% of the population is infected with HSV-1 and recurrent infections occur in one-third of individuals. Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore.

Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (see p. 1128), skin infections such as herpetic whitlow and erythema multiforme (see p. 1216).

HSV-2

The clinical features, diagnosis and management of genital herpes are described on page 168. The virus remains latent in the sacral ganglia and during recurrence, can produce a radiculomyelopathy, with pain in the groin, buttocks and upper thighs. Primary anorectal herpes infection is common

Figure 4.13 Primary herpes simplex type 1 (gingivostomatitis).

in men having sex with men (see p. 168). The clinical picture, diagnosis and treatment of genital herpes are described on page 169.

Neonates may develop primary HSV infection following vaginal delivery in the presence of active genital HSV infection in the mother, particularly if the maternal disease is a primary, rather than a recurrent infection. The disease in the baby varies from localized skin lesions (about 10–15%) to widespread visceral disease often with encephalitis, with a poor prognosis. Caesarean section should therefore be performed if active genital HSV infection is present during labour.

Immunocompromised patients such as those receiving intensive cancer chemotherapy or those with the acquired immunodeficiency syndrome (AIDS) may develop disseminated HSV infection involving many of the viscera. In severe cases, death may result from hepatitis and encephalitis. Eczema herpeticum is a serious complication in individuals with eczema, where the non-intact skin allows spread of lesions across large areas and bloodstream access which may lead to herpetic involvement of internal organs.

Humoral antibody develops following primary infection, but mononuclear cell responses probably prevent dissemination of disease.

Varicella zoster virus (VZV) infection

VZV produces two distinct diseases, varicella (chickenpox) and herpes zoster (shingles). The *primary infection* is chickenpox. It usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. In some countries (e.g. the Indian subcontinent), a different epidemiological pattern exists with most infections occurring in adulthood. Chickenpox rarely occurs twice in the same individual. Infectious virus is spread from the throat and from fresh skin lesions by air-borne transmission or direct contact. The period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. Following recovery from chickenpox, the virus remains latent in dorsal root and cranial nerve ganglia. *Reactivation* of infection then results in shingles.

Clinical features of chickenpox

Some 14–21 days after exposure to VZV, a brief prodromal illness of fever, headache and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours (Fig. 4.14). In young children, the prodromal illness may be very mild or absent. The illness tends to be more severe

in older children and can be debilitating in adults. The lesions occur on the face, scalp and trunk and to a lesser extent, on the extremities. It is characteristic to see skin lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually the pustules crust and heal without scarring.

Complications of chickenpox include pneumonia, which generally begins 1–6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children and cigarette smokers are at particular risk. Pulmonary symptoms are usually more striking than the physical findings, although a chest radiograph usually shows diffuse changes throughout both lung fields. CNS involvement occurs in about 1 per 1000 cases and most commonly presents as an acute truncal cerebellar ataxia. The immunocompromised are susceptible to disseminated infection with multiorgan involvement. Women in pregnancy are prone to severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus (if maternal infection is within the first 20 weeks of pregnancy, the risk of varicella embryopathy is 1–2%).

Clinical features of shingles

Shingles (see p. 1199) arises from the reactivation of virus latent within the dorsal root or cranial nerve ganglia. It may occur at all ages but is most common in the elderly, producing skin lesions similar to chickenpox, although classically they are unilateral and restricted to a sensory nerve (i.e. dermatomal) distribution (Fig. 4.15). The onset of the rash of shingles is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. Virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.

The commonest complication of shingles is post-herpetic neuralgia (PHN) (see p. 1129).

Diagnosis

The diseases are usually recognized clinically but can be confirmed by detection of VZV DNA within vesicular fluid using PCR, electron microscopy, immunofluorescence or culture of vesicular fluid and by serology.

Prophylaxis and treatment

Chickenpox usually requires no treatment in healthy children and infection results in lifelong immunity. Aciclovir and derivatives are, however, licensed for this indication in the USA,

Figure 4.14 Chickenpox in an adult. Generalized VZV.

Figure 4.15 Shingles – VZV affecting a dermatome. (Reproduced with kind permission of Imperial College School of Medicine.)

where the argument for treatment is one of health economics, viz. the sooner the child recovers, the sooner the carer can return to work. However, the disease may be fatal in the immunocompromised, who should therefore be offered protection, after exposure to the virus, with zoster-immune globulin (ZIG) and high-dose aciclovir at the first sign of development of the disease.

Anyone with chickenpox who is over the age of 16 years should be given antiviral therapy with aciclovir or a similar drug, if they present within 72 h of onset. Prophylactic ZIG is recommended for susceptible pregnant women exposed to varicella zoster virus and, if chickenpox develops, aciclovir treatment should be given (NB: aciclovir has not been licensed for use in pregnant women). If a woman has chickenpox at term, her baby should be protected by ZIG if delivery occurs within 7 days of the onset of the mother's rash. An effective live attenuated varicella vaccine is licensed as a routine vaccination of childhood in the USA; it is available on a named-patient basis in the UK and also for susceptible healthcare workers.

Shingles involving motor nerves, e.g. 7th cranial nerve leading to facial palsy, is also treated with aciclovir (or derivatives thereof) as the duration of lesion formation and time to healing can be reduced by early treatment. Aciclovir, valaciclovir and famciclovir have all been shown to reduce the burden of post-herpetic neuralgia when treatment is given in the acute phase. Shingles involving the ophthalmic division of the trigeminal nerve has an associated 50% incidence of acute and chronic ophthalmic complications. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles, no matter how mild the attack appears when it first presents.

Vaccination of all adults over the age of 60, with a dose higher than that used for chickenpox prophylaxis in childhood, reduces shingles-related morbidity and post-herpetic neuralgia and is recommended for all people in the USA.

Cytomegalovirus (CMV) infection

Clinically significant CMV infection arises particularly in two patient groups: fetuses who acquire the infection transplacentally and are born congenitally infected and patients who are immunosuppressed, e.g. transplant recipients or patients with HIV infection. As with all herpesviruses, the virus persists for life, usually as a latent infection in which the naked DNA is situated extrachromosomally in the nuclei of the cells in the endothelium of the arterial wall and in T lymphocytes. Over 50% of the adult population have serological evidence of latent CMV infection.

Clinical features

In healthy children and adults, CMV infection is usually asymptomatic but may cause an illness similar to infectious mononucleosis, with fever, occasionally lymphocytosis with atypical lymphocytes and hepatitis with or without jaundice. The Paul-Bunnell test for heterophile antibody is negative. Infection may be spread in saliva (accounting for extensive person-to-person spread in childcare units), sexual intercourse or blood transfusion and transplacentally to the fetus. Disseminated fatal infection with widespread visceral involvement occurs in the immunocompromised (see p. 190) and may cause encephalitis, retinitis, pneumonitis and diffuse involvement of the gastrointestinal tract.

Intrauterine infection may arise from either primary or reactivated maternal infection. CMV is, by far, the commonest congenital infection – in developed countries, such as the

Figure 4.16 Typical 'owl's eye' inclusion-bearing cell infected with cytomegalovirus.

UK, 0.3–1% of all babies are born congenitally infected with CMV. Around 5–10% of such babies have severe disease evident at birth, with a poor prognosis. CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatosplenomegaly are common and thrombocytopenia and haemolytic anaemia also occur. Periventricular calcification is seen on skull X-ray. A further 5–10% of infected babies are normal at birth, but developmental abnormalities become apparent later, e.g. sensorineural nerve deafness. The remaining 80–85% of infected babies are normal at birth and develop normally.

Diagnosis

Serological tests can identify latent (IgG) or primary (IgM) infection. However, most infections are now diagnosed by detection and quantification of CMV DNA or RNA using molecular amplification techniques, in blood or other body fluid samples. The virus can also be identified in tissues by the presence of characteristic intranuclear 'owl's eye' inclusions (Fig. 4.16) on histological staining and by direct immunofluorescence. Culture in human embryo fibroblasts is usually slow but diagnosis can be accelerated by immunofluorescent detection of antigen in the cultures.

Treatment

In the immunocompetent, infection is usually self-limiting and no specific treatment is required. In the immunosuppressed, ganciclovir (5 mg/kg twice daily for 14–21 days) reduces retinitis and gastrointestinal damage and can eliminate CMV from blood, urine and respiratory secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, particularly those with AIDS, maintenance therapy may be necessary. Drug resistance has been reported in AIDS patients and transplant recipients. Bone marrow toxicity is common. Valganciclovir, foscarnet and cidofovir are also available (see p. 93). Treatment of CMV in neonates is difficult, but ganciclovir therapy of infected babies with evident CNS involvement has been shown to improve long-term hearing outcome.

Epstein-Barr virus (EBV) infection

Globally, most individuals are infected with this virus at an early age (0–5 years), at which time clinical symptoms are unusual. Infection at an older age is associated with an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs worldwide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

FURTHER READING

Luzuriaga K, Sullivan JL. Infectious mononucleosis. *N Engl J Med* 2010; 362: 1993–2000.

Clinical features

The predominant symptoms of infectious mononucleosis are fever, headache, malaise and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, but other complications such as myocarditis, meningitis, encephalitis, mesenteric adenitis and splenic rupture are rare. Splenic rupture occurs in the first 3 weeks of illness and contact sport should be avoided during this period.

Although some young adults remain debilitated and depressed for some months after infection, the evidence for reactivation of latent virus in healthy individuals is controversial, although this is thought to occur in immunocompromised patients.

Following primary infection, EBV remains latent in resting memory B lymphocytes. It has been shown *in vitro* that of nearly 100 viral genes expressed during replication, approximately only 10 are expressed in the latently infected B cells.

Severe, often fatal infectious mononucleosis may result from a rare X-linked lymphoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and/or lymphoma.

EBV is the cause of oral hairy leucoplakia in AIDS patients and is intimately linked to the generation of a number of malignancies, including Burkitt's lymphoma, undifferentiated nasopharyngeal carcinoma, post-transplant lymphoma, the immunoblastic lymphoma of AIDS patients, some forms of Hodgkin's lymphoma and gastric cancer. Different levels of expression of EBV latency genes occur in these proliferative conditions caused by the virus and various co-factors are also involved in their pathogenesis, e.g. in Burkitt's lymphoma, the commonest tumour of childhood in sub-Saharan Africa, epidemiological evidence points to an interplay between EBV infection and the presence of hyperendemic (i.e. present all year-round) malaria. EBV is a cause of haemophagocytic lymphohistiocytosis (HLH) (see p. 379). HLH is an uncommon condition presenting with fever, rash, jaundice, hepatosplenomegaly and enlarged lymph nodes. Blood tests show cytopenia, a high ferritin and the bone marrow shows haemophagocytosis. It can be primary (inherited) or secondary, e.g. EBV, and has a high mortality.

Diagnosis

EBV infection should be strongly suspected if atypical mononuclear cells (activated CD8 positive T lymphocytes) are found in the peripheral blood. It can be confirmed during the second week of infection by a positive Paul-Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes, in around 90% of cases. False positives can occur in other conditions such as viral hepatitis, Hodgkin's lymphoma and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by CMV, toxoplasmosis and acute HIV infection (the so-called seroconversion illness) but these can be distinguished serologically.

Treatment

The majority of cases require no specific treatment and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g. encephalitis, meningitis, Guillain-Barré syndrome), when there is marked

thrombocytopenia or haemolysis, or when the tonsillar enlargement is so marked as to cause respiratory obstruction.

Human herpesvirus type 6 (HHV-6)

This human herpesvirus infects CD4⁺ T lymphocytes, occurs worldwide and exists as a latent infection in over 85% of the adult population. It is spread by contact with oral secretions. The virus causes roseola infantum (*exanthem subitum*), which presents as a high fever followed by generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions and aseptic meningitis or encephalitis occur as rare complications. Reactivation in the immunocompromised may lead to severe pneumonia.

Treatment

Supportive management only is recommended for the common infantile disease. Ganciclovir can be used in the immunocompromised.

Human herpesvirus type 7 (HHV-7)

This virus is similar to HHV-6 in being a T lymphotropic herpesvirus. It is also present as a latent infection in over 85% of the adult population and it is known to infect CD4⁺ helper T cells by using the CD4 antigen (the main receptor employed by HIV). The full spectrum of disease due to HHV-7 has not yet been fully characterized, but, like HHV-6, it may cause roseola infantum in infants.

Human herpesvirus type 8 (Kaposi's sarcoma-associated herpesvirus)

This human herpesvirus is strongly associated with the aetiology of all forms of Kaposi's sarcoma. Antibody prevalence is high in those with tumours but relatively low in the general population of most industrialized countries. High rates of infection (>50% population) have been described in central and southern Africa and this matches the geographic distribution of classical Kaposi's sarcoma before the era of AIDS. HHV-8 is transmitted sexually and through exposure to blood from needle sharing. It is thought that salivary transmission may be the predominant route in Africa. HHV-8 RNA transcripts have been detected in Kaposi's sarcoma cells and in circulating mononuclear cells from patients with the tumour. This virus also has an aetiological role in two rare lymphoproliferative diseases – multicentric *Castleman's disease* (a disorder of the plasma cell type) and *primary effusion lymphoma* (body-cavity-based lymphoma), which is characterized by pleural, pericardial or peritoneal lymphomatous effusions in the absence of a solid tumour mass.

Papovaviruses

This virus family originally comprised the *papilloma*, *polyoma* and *vacuolar* viruses, although the polyomaviruses have now been reclassified into a separate family. These viruses tend to produce chronic infections, often with evidence of latency. They are capable of inducing neoplasia in some animal species and were among the first viruses to be implicated in tumorigenesis. Human papillomaviruses, of which there are at least 100 types, are responsible for the common skin and genital warts and certain types (mainly 16 and 18) are the cause of carcinoma of the cervix and some oral cancers (type 16). The realization that cancer of the cervix is an infectious disease has led to the development of papillomavirus vaccines, which have been shown to prevent disease associated

with the high-risk HPV types 16 and 18 and have recently been licensed for use in the USA, Australia and Europe. The current recommendations in many countries are for vaccination of all girls at age 9–14 years. It may also be sensible to vaccinate boys, but this strategy is much less cost-effective. (For *genital warts* see [page 169](#).)

The *human BK virus*, a polyomavirus, is generally found in immunocompromised individuals and may be detected in the urine of 15–40% of renal transplant patients. Rarely, this is associated with impairment of function of the transplanted kidney – BK nephropathy. JC virus, also a polyomavirus, is the cause of progressive multifocal leucoencephalopathy (PML), which presents as dementia in the immunocompromised and is due to progressive cerebral destruction resulting from accumulation of the virus in brain tissue. WU and KI polyomaviruses have been recently identified. These may be associated with respiratory tract infections in young children. Merkel cell polyomavirus has been identified in the malignant tissue of the rare Merkel cell carcinoma of the skin.

Erythroviruses

Human erythrovirus B19 causes erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the ‘slapped-cheek’ appearance). The patient is well and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Nonspecific respiratory tract illness is another common manifestation of infection. Moderately severe self-limiting polyarthropathy (see [p. 519](#)) is common if infection occurs in adulthood, especially in women. Aplastic crisis may occur in patients with chronic haemolysis (e.g. sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from infection during the first and second trimesters of pregnancy.

Bocavirus is a recently identified erythrovirus, which accounts for around 3–5% of respiratory tract infections in young children.

Poxviruses

Smallpox (variola)

This disease was eradicated in 1977 following an aggressive vaccination policy and careful detection of new cases coordinated by the World Health Organization. Its possible use in bioterrorism has resulted in the reintroduction of smallpox vaccination in some countries (see [p. 935](#)).

Monkeypox

This is a rare zoonosis that occurs in small villages in the tropical rainforests in several countries of West and Central Africa. Its clinical effects, including a generalized vesicular rash, are indistinguishable from smallpox, but person-to-person transmission is unusual. Most infections occur in children who have not been vaccinated against smallpox. Disease can be severe, with mortality rates of 10–15% in unvaccinated individuals. Serological surveys indicate that several species of squirrel are likely to represent the animal reservoir. The virus was introduced into the USA in 2003 via West African small mammals illegally imported as pets. Widespread infection of prairie dogs resulted and there were 37 laboratory confirmed cases in humans, only two of which suffered complications (keratitis, encephalopathy).

Cowpox

Cowpox produces large vesicles which are classically on the hands in those in contact with infected cows. The lesions are

associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species including domestic and wild cats and the reservoir is thought to exist in a range of rodents.

Vaccinia virus

This is a laboratory virus and does not occur in nature in either humans or animals. Its origins are uncertain but it has been invaluable in its use as the vaccine to prevent smallpox. Vaccination is now not recommended except for laboratory personnel handling certain poxviruses for experimental purposes or in contingency planning to manage a deliberate release of smallpox virus. It is being assessed experimentally as a possible carrier for new vaccines.

Orf

This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans (see [p. 1199](#)).

Molluscum contagiosum

This is discussed on [page 1200](#).

Hepadna viruses

These partially double-stranded DNA viruses infect a number of species. The representative virus from this family which infects humans, hepatitis B virus, is discussed, along with other hepatitis viruses, on [page 317](#).

RNA VIRUSES (Table 4.18)

Picornaviruses (PICO = small)

This is a large family of small RNA viruses, which includes the enteroviruses and rhinoviruses which infect humans and also hepatitis A virus (see [p. 316](#)). The term enterovirus refers to the enteric means of spread of these viruses, i.e. via the faeco-oral route. The enteroviruses include poliovirus types 1–3, Cxsackie A and B viruses, echoviruses and enteroviruses (EV) 68–71. There are several newly described EVs yet to be officially classified.

Poliovirus infection (poliomyelitis)

Poliomyelitis occurs when a susceptible individual is infected with poliovirus type 1, 2 or 3. These viruses have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial motor neurones. Poliomyelitis was found worldwide but its incidence has decreased dramatically following improvements in sanitation, hygiene and the widespread use of polio vaccines. Spread is usually via the faeco-oral route, as the virus is excreted in the faeces.

Clinical features

The incubation period is 7–14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably. The commonest outcome (95% of individuals) is asymptomatic seroconversion.

- **Abortive poliomyelitis** occurs in approximately 4–5% of cases, characterized by the presence of fever, sore throat and myalgia. The illness is self-limiting and of short duration.
- **Non-paralytic poliomyelitis** (poliovirus meningitis) has features of abortive poliomyelitis as well as signs of meningeal irritation, but recovery is complete.

- **Paralytic poliomyelitis** occurs in approximately 0.1% of infected children (1.3% of adults). Factors predisposing to the development of paralysis include male sex, exercise early in the illness, trauma, surgery or intramuscular injection, which localize the paralysis, and recent tonsillectomy (bulbar poliomyelitis).

The paralytic form of the disease follows about 4–5 days after an initial illness simulating abortive poliomyelitis. Meningeal irritation and muscle pain recur and are followed by the onset of asymmetric flaccid paralysis without sensory involvement. The paralysis is usually confined to the lower limbs in children under 5 years of age and the upper limbs in older children, whereas in adults it manifests as paraplegia or quadriplegia.

Bulbar poliomyelitis

Bulbar poliomyelitis is characterized by the presence of cranial nerve involvement and respiratory muscle paralysis. Soft palate, pharyngeal and laryngeal muscle palsies are common.

Aspiration pneumonia, myocarditis, paralytic ileus and urinary calculi are late complications of poliomyelitis.

Diagnosis

The diagnosis is a clinical one. Distinction from Guillain–Barré syndrome is easily made by the absence of sensory involvement and the asymmetrical nature of the paralysis in poliomyelitis. Laboratory confirmation and distinction between the wild virus and vaccine strains is achieved by genome detection techniques, virus culture, neutralization and temperature marker tests.

Treatment

Treatment is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved. Once the acute phase of the illness has subsided, occupational therapy, physiotherapy and occasionally surgery have roles in patient rehabilitation.

Prevention and control

Immunization (Box 4.6) has dramatically decreased the prevalence of this disease worldwide and global eradication of the virus, coordinated by the World Health Organization, is

Table 4.19 Picornavirus infections (excluding poliovirus and rhinovirus)

within reach. The virus remains endemic in only four countries: Nigeria, India, Pakistan and Afghanistan. However, there have been outbreaks in West Africa where cultural taboos have disrupted the polio vaccination campaign and also in the Sudan, with spread of disease into neighbouring countries. New preparations of inactivated IM poliovirus vaccine (IPV) have greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use oral polio vaccine (OPV) in countries free from poliomyelitis, mean that IPV has replaced OPV in the routine immunization schedules in many countries.

Coxsackievirus, echovirus and other enterovirus infections

These viruses are also spread by the faeco-oral route. They each have a number of different types and are responsible for a broad spectrum of disease involving the skin and mucous membranes, muscles, nerves, the heart (Table 4.19) and, rarely, other organs, such as the liver and pancreas. They are frequently associated with pyrexial illnesses and are the most common cause of aseptic meningitis.

Herpangina

This disease is mainly caused by Coxsackie A viruses and presents with a vesicular eruption on the fauces, palate and uvula. The lesions evolve into ulcers. The illness is usually associated with fever and headache but is short-lived, recovery occurring within a few days.

Hand, foot and mouth disease

This disease is mainly caused by Coxsackievirus A16 or A10. It is also the main feature of infection with enterovirus (EV)71. Oral lesions are similar to those seen in herpangina but may be more extensive in the oropharynx. Vesicles and a maculopapular eruption also appear, typically on the palms of the hands and the soles of the feet, but also on other parts of the body. This infection commonly affects children. Recovery occurs within a week.

Neurological disease

Other enteroviruses in addition to poliovirus can cause a broad range of neurological disease, including meningitis, encephalitis and a paralytic disease similar to poliomyelitis. EV71 has particular predilection for neuroinvasion. Thus, in

epidemics of EV71 infection, a variety of serious neuromotor syndromes arise, albeit in a minority of those infected.

Heart and muscle disease

Enterovirus infection is a cause of acute myocarditis and pericarditis, from which, in general, there is complete recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis.

Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of Bornholm disease, a febrile illness usually due to Coxsackievirus B. The pain may be of such an intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults and may be complicated by meningitis or cardiac involvement.

Rhinovirus infection

Rhinoviruses are responsible for the common cold (see p. 808). Chimpanzees and humans are the only species to develop the common cold. ICAM-1 is a cellular receptor for rhinoviruses and only these two species have the specific binding domain. Peak incidence rates occur in the colder months, especially spring and autumn. There are multiple rhinovirus immunotypes (>100), which makes vaccine control impracticable. In contrast to enteroviruses, which replicate at 37°C, rhinoviruses grow best at 33°C (the temperature of the upper respiratory tract), which explains the localized disease characteristic of common colds.

Reoviruses

Reoviruses are a large family of viruses with double-stranded RNA segmented genomes.

Rotavirus infection

Rotavirus (Latin *rota* = wheel) is so named because of its electron microscopic appearance with a characteristic circular outline with radiating spokes (Fig. 4.17). It is responsible worldwide for both sporadic cases and epidemics of diarrhoea and is the commonest cause of childhood diarrhoea. More than 500 000 infected children under the age of 5 years are estimated to die annually in resource-deprived countries, compared with 75–150 in the USA. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic infections are common and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

Bhutta ZA. The last mile in global poliomyelitis eradication. *Lancet* 2011; 378:549–552.

Figure 4.17 Electronmicrograph of human rotavirus.

Adults may become infected with rotavirus but symptoms are usually mild or absent. The virus may, however, cause diarrhoea in immunosuppressed adults, or outbreaks in patients on care of the elderly wards.

Clinical features

The illness is characterized by vomiting, fever, diarrhoea and the metabolic consequences of water and electrolyte loss.

Diagnosis and differential diagnosis

The diagnosis can be established by PCR for genome detection, or ELISA for the detection of rotavirus antigen in faeces and by electron microscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia and mononuclear cell infiltration of the lamina propria.

Treatment and prevention

Treatment is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (see Box 4.10). Antibiotics should not be prescribed. A controlled trial in Egypt in children with rotavirus diarrhoea demonstrated faster recovery (31 h vs 75 h) in those given nitazoxanide, a broad-spectrum anti-infective agent, for 3 days compared with placebo.

Rotavirus vaccines

Despite a major setback when the first licensed rotavirus vaccine was rapidly withdrawn from the market in 1999 following reports of increased rates of intussusception, two new vaccines have been developed and are now used in many countries. Both are live vaccines. One vaccine contains an attenuated human strain with the relevant antigens being P[8] and G1, while another is based on a bovine parent strain and comprises five single-gene reassortants each containing a human-strain outer capsid gene encoding the most common human antigenic types (P[8] and G1–4).

Caliciviruses

This extensive virus family, named after the cup-shaped (Latin *calyx* = cup) indentations on their viral surface seen by electron microscopy, contains four genera, two of which, the noroviruses and sapoviruses, infect humans and cause gastroenteritis.

Norovirus is the major cause of acute non-bacterial gastroenteritis, causing outbreaks in nursing homes, hospitals, schools, leisure centres, restaurants and cruise ships.

Box 4.7 Arbovirus (arthropod-borne) infection

Defining features of arboviruses

- Zoonotic viruses, transmitted through the bites of insects, especially mosquitoes and ticks.
- >385 viruses are classified as arboviruses.
- Most are members of the Togavirus, Flavivirus and Bunyavirus families (see Table 4.21).
- *Culex*, *Aedes* and *Anopheles* mosquitoes account for transmission of the majority of these viruses.

Clinical features of arbovirus infection

- Most arbovirus diseases are generally mild; epidemics are frequent and when these occur, the mortality is high.
- In general, short incubation period (<10 days). Common features include a biphasic illness, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia and arthralgia. Lymphadenopathy is seen in dengue.
- **Haemorrhage** (from increased vascular permeability, capillary fragility, consumptive coagulopathy) is a feature of some arbovirus infections (see Table 4.23).
- **Encephalitis** resulting from cerebral invasion may be prominent in some arbovirus fevers.

Transmission is mostly faeco-oral with outbreaks suggesting a common source, such as food and water and fomites. Aerosol transmission also occurs and noroviruses can be detected in vomit. Illness is usually self-limiting (12–48 hours) and mild, consisting of nausea, headache and abdominal cramps, followed by diarrhoea and vomiting, which may be the only feature (winter vomiting). Diagnosis is by demonstration of viral nucleic acid or antigen in diarrhoeal faeces. Treatment is with oral rehydration solutions (ORS). Prevention can be difficult but handwashing and good hygienic food preparation is required.

Sapovirus causes gastroenteritis, mainly in children.

Other viruses associated with gastroenteritis are shown in Table 4.20.

Togaviruses

This family comprises two genera: the rubiviruses, which include rubella virus; and the alphaviruses, which include some of the *arthropod-borne viruses* (see Box 4.7 and Table 4.21).

Rubella

Rubella ('German measles') is caused by a spherical, enveloped RNA virus which is easily killed by heat and ultraviolet light. While the disease can occur sporadically, epidemics are not uncommon. It has a worldwide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

Clinical features

The incubation period is 14–21 days, averaging 18 days. The clinical features are largely determined by age, with symptoms being mild or absent in children under 5 years.

During the prodrome, the patient may develop malaise and fever and mild conjunctivitis and lymphadenopathy involving particularly the suboccipital, postauricular and posterior

Figure 4.18 Rubella rash.

cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and limbs. It is pinkish red, macular and discrete, although some of these lesions may coalesce (Fig. 4.18). It usually fades by the second day and rarely persists beyond 3 days after its appearance.

Complications

Complications are rare. They include superadded pulmonary bacterial infection, arthralgia (commoner in females), haemorrhagic manifestations due to thrombocytopenia, encephalitis and the congenital rubella syndrome. Rubella affects the fetuses of up to 80% of all women who contract the infection during the 1st trimester of pregnancy. The incidence of congenital abnormalities diminishes in the 2nd trimester and no ill-effects result from infection in the 3rd trimester.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations, especially patent ductus arteriosus and ventricular septal defect, eye lesions (especially cataracts), microcephaly, mental retardation and deafness. Hepatosplenomegaly, myocarditis, interstitial pneumonia and metaphyseal bone lesions also occur.

Diagnosis and treatment

The diagnosis is clinical, but laboratory diagnosis is essential (especially in pregnancy) to distinguish the illness from other virus infections (e.g. erythrovirus B19, echovirus) and drug rashes. This is achieved by the detection of rubella-specific IgM by ELISA in an acute serum sample, preferably confirmed by the demonstration of IgG seroconversion (or a rising titre of IgG) in a subsequent sample taken 14 days later. Viral genome can be detected in throat swabs (or oral fluid samples), urine and, in the case of intrauterine infection, the products of conception.

Treatment is supportive.

Prevention

Human immunoglobulin can decrease the symptoms of this already mild illness, but does not prevent the teratogenic effects. Several live attenuated rubella vaccines have been used with great success in preventing this illness and these have been successfully combined with measles and mumps vaccines in the MMR vaccine. The side-effects of vaccination have been dramatically decreased by using vaccines prepared in human embryonic fibroblast cultures (RA 27/3 vaccine). Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

Alphaviruses

The 29 viruses of this group are all transmitted by mosquitoes; eight result in human disease (see Box 4.7 and Table 4.21). These viruses are globally distributed and tend to acquire their names from the location where they were first isolated (such as *Ross River*, *Eastern*, *Venezuelan* and *Western equine encephalitis viruses*) or by the local expression for a major symptom caused by the virus (such as chikungunya, meaning 'doubled up'). Infection is characterized by fever, headache, maculopapular skin rash, arthralgia, myalgia and sometimes encephalitis.

Major epidemics of chikungunya were reported in India, Sri Lanka and islands in the Indian Ocean (including Reunion, Mauritius and the Seychelles) in 2005 and 2006, with at least 1 million cases and several hundred deaths. The severity of these epidemics is possibly due to a viral strain

with mutations resulting in a higher neurovirulence. Several European countries reported cases of chikungunya in returning travellers – including 133 cases in the UK in 2006. The virus may now populate the local *Aedes* mosquito via increased numbers of travellers who may import virus into countries where it has not previously been described, e.g. an outbreak in Italy in 2007 involved over 150 cases with one death and two locally-acquired confirmed cases were reported from the French mainland in 2010.

Flaviviruses

There are 60 viruses in this group, some of which are transmitted by ticks and others by mosquitoes. Hepatitis C virus (see p. 323) is also a flavivirus.

Yellow fever

Yellow fever, caused by a flavivirus, is an illness of widely varying severity. It is confined to Africa (90% of cases) and South America between latitudes 15°N and 15°S. For poorly understood reasons, yellow fever has not been reported from Asia, despite the fact that climatic conditions are suitable and the vector, *Aedes aegypti*, is common. The infection is transmitted in the wild by *A. africanus* in Africa and the *Haemagogus* species in South and Central America. Extension of infection to humans (via the mosquito from monkeys) leads to the occurrence of 'jungle' yellow fever. *A. aegypti*, a domestic mosquito which lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). Once infected, a mosquito remains so for life.

Clinical features

The incubation period is 3–6 days. Mild infection is indistinguishable from other viral fevers such as influenza or dengue.

Three phases in the severe (classical) illness are recognized. Initially, the patient presents with a high fever of acute onset, usually 39–40°C, which then returns to normal in 4–5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe. Relative bradycardia (Faget's sign) is present from the second day of illness. The patient then makes an apparent recovery and feels well for several days. Following this 'phase of calm', the patient again develops increasing fever, deepening jaundice and hepatomegaly. Ecchymosis, bleeding from the gums, haematemesis and melaena may occur. Coma, which is usually a result of uraemia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. The pathology of the liver shows mid-zone necrosis and eosinophilic degeneration of hepatocytes (Councilman bodies) (see p. 316).

Diagnosis and treatment

The diagnosis is established by a history of travel and vaccination status and by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible, but in endemic areas cross-reactivity with other flaviviruses is a problem.

Treatment is supportive. Bed rest (under mosquito nets), analgesics and maintenance of fluid and electrolyte balance are required.

Prevention and control

Yellow fever is an internationally notifiable disease. It is easily prevented using the attenuated 17D chick embryo vaccine

but concerns over safety have arisen because of infection with the 17D virus. Vaccination is not recommended for children under 9 months or immunosuppressed patients, unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO Expanded Programme of Immunization includes yellow fever vaccination in endemic areas.

Dengue

This is the commonest arthropod-borne viral infection in humans: over 100 million cases occur every year in the tropics, with over 10 000 deaths from dengue haemorrhagic fever. Dengue is caused by a flavivirus and is found mainly in Asia, South America and Africa, although it has been reported from the USA and, more recently, in Italy.

Four different antigenic varieties of dengue virus are recognized and all are transmitted by the daytime-biting *A. aegypti*, which breeds in standing water in refuse dumps in inner cities. *A. albopictus* is a less common transmitter. Humans are infective during the first 3 days of the illness (the viraemic stage). Mosquitoes become infective about 2 weeks after feeding on an infected individual and remain so for life. The disease is usually endemic. Heterotypic immunity between serotypes after the illness is partial and lasts only a few months, although homotypic immunity is lifelong.

Clinical features

The incubation period is 5–6 days following the mosquito bite. Asymptomatic or mild infections are common. Two clinical forms are recognized (Fig. 4.19).

Classic dengue fever

Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain which worsens on eye movements, conjunctival suffusion and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate and transient, morbilliform skin rashes may also appear on the limbs with subsequent spread to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3–4 days, the temperature returns to normal for a couple of days and then the fever returns, together with the features already mentioned, but milder. This biphasic or 'saddleback' pattern is considered characteristic. Severe fatigue, a feeling of being unwell and depression are common for several weeks after the fever has subsided.

Dengue haemorrhagic fever (DHF)

Dengue haemorrhagic fever is a severe form of dengue fever and is believed to be the result of two or more sequential infections with different dengue serotypes. It is characterized by the capillary leak syndrome, thrombocytopenia, haemorrhage, hypotension and shock. It is characteristically a disease of children, occurring most commonly in South-east Asia. The disease has a mild start, often with symptoms of an upper respiratory tract infection. This is then followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis and melaena known as the dengue shock syndrome. This has a mortality of up to 44%. Serum complement levels are depressed and there is laboratory evidence of a consumptive coagulopathy.

Diagnosis and treatment

- Isolation of dengue virus by tissue culture, or detection of viral RNA by PCR in sera obtained during the first few days of illness is diagnostic.

Figure 4.19 Dengue infection – course and timing of diagnosis. (Reprinted from Halstead SB. *Dengue*. Lancet 2007; 370:1644–1652, with permission from Elsevier.)

- Detection of virus-specific IgM antibodies, or of rising IgG titres in sequential serum samples, haemagglutination inhibition, 'ELISA' or complement-fixation assays confirm the diagnosis.
- Blood tests show leucopenia and thrombocytopenia.

Treatment is supportive with analgesics and adequate fluid replacement. Corticosteroids are of no benefit and convalescence can be slow. In DHF, blood transfusion may be necessary.

Prevention

Travellers should be advised to sleep under impregnated nets but this is not very effective as the mosquito bites in daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays and breeding sites, e.g. small stagnant water pools, should be eradicated. There is no effective vaccine yet although some are being trialled.

Japanese encephalitis

Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently from the rice-growing countries of South-east Asia and the Far East. *Culex tritaeniorhynchus* is the usual vector and this feeds mainly on pigs as well as birds such as herons and sparrows. Humans are accidental hosts.

As with other viral infections, the clinical manifestations are variable. The incubation period is 5–15 days. Most infections are asymptomatic. When disease arises, the onset is heralded by severe rigors. Fever, headache and malaise last 1–6 days. Weight loss is prominent. In the acute encephalitic stage, the fever is high (38–41°C), neck rigidity occurs and neurological signs such as altered consciousness, hemiparesis and convulsions develop. Mental deterioration occurs over a period of 3–4 days and culminates in coma. Mortality varies from 7% to 40% and is higher in children. Residual neurological defects such as deafness, emotional lability and hemiparesis occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged. Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. Vaccines containing formalin-inactivated viruses derived from mouse brain are effective and available. Treatment is supportive.

West Nile virus

In 1999, West Nile virus was first recognized in the western hemisphere (New York, USA) having been previously reported in Africa, Asia and parts of Europe. By the end of 2009, the US outbreak had resulted in over 25 000 human cases and over 1100 deaths. The vast majority of infections are asymptomatic. In a minority of cases, infection presents as a febrile illness, with a maculopapular rash, with 1% resulting in severe encephalitis. Disease severity and mortality is age-related, being greatest in the elderly. The primary hosts of infection are birds. It is spread by mosquitoes and may also infect humans and horses. It can also be transmitted by blood transfusions, breast-feeding and organ donation from an infected individual. Diagnosis is by genome detection in appropriate samples, or specialized serology for the detection of IgM virus-specific antibodies.

Tick-borne encephalitis virus (TBEV)

This flavivirus (actually a series of closely related viruses) is transmitted by *Ixodes* spp. ticks. It occurs in an area extending from Western Europe to Japan. The tick is the main reservoir for the virus, which is transmitted when it feeds on mice and other rodents.

The disease starts 4–28 days after a bite from an infected tick and is biphasic in 80% of patients. Fever, malaise, headache and fatigue are followed, after a symptom-free period of about 7 days, by encephalitis. There may be associated limb paralysis which is due to anterior horn cell involvement mainly of the cervical region. Cranial nerve involvement also occurs. TBEV IgM and IgG antibodies are present and the virus can be detected in blood by RT-PCR. Overall mortality is about 1% (but can be considerably higher for certain strains) but 30% have impairment in neurological function with persistent paralysis in 6%. A preventative vaccine is available.

Bunyaviruses

Bunyaviruses belong to a large family of more than 200 viruses, grouped into a number of genera, most of which are arthropod-borne.

FURTHER READING

Lindquist L, Vapalahti O. Tick-borne encephalitis. *Lancet* 2008; 371:1861–1871.

Congo-Crimean haemorrhagic fever

This widespread disease, caused by a virus of the *nairovirus* genus of bunyaviruses, is found mainly in Asia and Africa. The primary hosts are cattle and hares and the vectors are the *Hyalomma* ticks. Following an incubation period of 3–6 days there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality is 10–50%.

Hantaviruses

Hantaviruses belong to the *Hantavirus* genus of bunyaviruses and are enzootic viruses of wild rodents which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (or haemorrhagic fever with renal syndrome, HFRS). This condition has a mortality of 5–10% and is characterized by fever, shock and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g. Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement. It is seen in Scandinavia and in other European countries in people who have been in contact with bank voles. In the USA, a Hantavirus (transmitted by the deer mouse) termed Sin Nombre was identified as the cause of outbreaks of acute respiratory disease (Hantavirus pulmonary syndrome, HPS) in adults. Other Hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of Hantavirus infection is made by an ELISA technique for specific antibodies.

Rift Valley fever

Rift Valley fever, caused by a virus from the *phlebovirus* genus of bunyaviruses, is primarily an acute febrile illness of livestock: sheep, goats and camels. It is found in southern and eastern Africa. The vector in East Africa is *Culex pipiens* and in southern Africa, *Aedes caballus*, but it can be transmitted by the bite of an infected animal. Following an incubation period of 3–6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts 2–4 days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations and hepatic necrosis. Mortality approaches 50% in severe forms of the illness. Treatment is supportive. Animals can be vaccinated.

Orthomyxoviruses

Influenza

Three types of influenza virus are recognized: A, B and C, distinguishable by the nature of their internal proteins. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycoprotein, aids attachment of the virus to the surface of susceptible host cells at specific receptor sites. Cell penetration, probably by pinocytosis and release of replicated viruses from the cell surface effected by budding through the cell membrane, is facilitated by the action of the enzyme neuraminidase (N) which is also present on the viral envelope. Sixteen H subtypes (H1–H16) and nine N subtypes (N1–N9) have been identified for influenza A viruses but only H1, H2, H3 and N1 and N2 have established stable lineages in the human population since 1918.

- **Influenza A** is generally responsible for pandemics and epidemics.
- **Influenza B** often causes smaller or localized and milder outbreaks, such as in camps or schools. There are no subtypes of influenza B.
- **Influenza C** rarely produces disease in humans.

Antigenic shift generates new influenza A subtypes, which emerge at irregular intervals and give rise to influenza pandemics. Possible mechanisms include:

1. Genetic reassortment of the RNA of the virus (which is arranged in eight segments) with that of an avian influenza virus; this requires co-infection of a host with both human and avian viruses. The pig is one animal in which this may occur. Alternatively, humans may act as the mixing vessel.
2. Trans-species transmission of an avian influenza virus to humans. Viruses transmitted in this way are usually not well adapted to growth in their new host, but adaptation may occur as a result of spontaneous mutations, leading to the emergence of a pandemic strain.

Antigenic drift (minor changes in influenza A and B viruses) results from point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin and neuraminidase, which induce humoral immunity. This enables the virus to evade previously induced immune responses and is the process whereby annual influenza epidemics arise.

Thus, changes due to antigenic shift or drift render the individual's immune response less able to combat the new variant.

The most serious pandemic of influenza, caused by influenza A/H1N1, occurred in 1918 and was associated with more than 20 million deaths worldwide. In 1957, antigenic shift led to the appearance of influenza A/H2N2, which caused a worldwide pandemic. A further pandemic occurred in 1968 with the emergence of Hong Kong influenza A/H3N2 and minor antigenic drifts have caused outbreaks around the world ever since. In 1976, influenza A H1N1 reappeared, most likely as a result of accidental release from a laboratory and has since co-circulated with A/H3N2 and B viruses. In 1997, avian influenza A/H5N1 viruses were first isolated from humans, raising the spectre of another pandemic. As of July 2010, over 500 sporadic human A/H5N1 infections have been reported from 15 countries, mostly in Asia (Indonesia, China and Vietnam) and almost always arising from direct contact with infected chickens, with a mortality of >50%. However, while this virus is highly pathogenic to humans, due to the induction of a cytokine storm within the lungs, it still has not evolved to replicate well in human cells and human-to-human spread is unusual. However, anxieties remain that either genetic reassortment will occur in a human co-infected with human A/H1N1 or A/H3N2 viruses, or adaptive mutations will occur within infected human hosts, such that a truly pandemic strain will emerge.

In April 2009, a novel influenza A virus (H1N1) was identified in patients with severe respiratory illness in Mexico and North America. The virus quickly spread across the world, with the WHO declaring an official pandemic on 11 June 2009. The virus was the end product of several reassortments between pre-existing swine, avian and human virus lineages, with the swine H1 protein showing around 20% amino acid sequence divergence from previously circulating human seasonal H1N1 influenza viruses. The virus is variably referred to as 'swine H1N1', '2009 H1N1' or 'H1N1v', where 'v' stands for variant. Although unquestionably highly transmissible (with estimates of millions of infections worldwide

FURTHER READING

Beishe R. Implications of the emergence of a novel H1 influenza virus. *N Engl J Med* 2009; 360: 2663–2668.

Uyeki TM. 2009 H1N1 virus transmission and outbreaks. *N Engl J Med* 2010; 362: 2221–2223.

within 1 year), this pandemic virus was (perhaps fortunately), not especially virulent. Most infections occurred in children – adults over 50 years of age had evidence of pre-existing protective immunity. A minority of infections resulted in serious disease, with an estimated symptomatic case-fatality ratio of 0.04% (equating to around 500 deaths) in the UK. Worldwide, around 20 000 deaths in laboratory confirmed cases have been reported to the WHO. Risk factors for serious disease included pre-existing underlying medical conditions, age <5 years, obesity and pregnancy. The pandemic was declared officially over by the WHO in August 2010, with the virus now expected to behave as a normal seasonal influenza virus, replacing the previously circulating A H1N1 virus.

Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

Sporadic cases of influenza and outbreaks among groups of people living in a confined environment are frequent. The incidence increases during the winter months. Spread is mainly by droplet infection but fomites and direct contact have also been implicated.

The clinical features, diagnosis, treatment and prophylaxis of influenza are discussed on page 811.

Paramyxoviruses

These are a heterogeneous group of enveloped viruses with negative single-stranded RNA genomes of varying size that are responsible for a variety of infections.

Parainfluenza

Parainfluenza is caused by the parainfluenza viruses types I–IV; these have a worldwide distribution and cause acute respiratory disease. Type IV appears to be less virulent than the other types and has been linked only to mild upper respiratory diseases in children and adults.

Parainfluenza is essentially a disease of children and presents with features similar to the common cold. When severe, a brassy cough with inspiratory stridor and features of laryngotracheitis (croup) are present. Fever usually lasts for 2–3 days and may be more prolonged if pneumonia develops. The development of croup is due to sub-mucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession and progressive airway obstruction. Infection in the immunocompromised is usually prolonged and may be severe. Treatment is supportive with oxygen, humidification and sedation when required. The role of steroids and the antiviral agent ribavirin is controversial.

Measles (rubeola)

Measles is a highly communicable disease that occurs worldwide. With the introduction of aggressive immunization policies, the incidence of measles has fallen dramatically in the West but there are an estimated 0.2 million deaths annually due to measles infection worldwide, mostly in Africa and South-east Asia, with mortality being highest in children younger than 12 months of age. It is spread by droplet infection and the period of infectivity is from 4 days before until 2 days after the onset of the rash.

Clinical features

The incubation period is 8–14 days. Two distinct phases of the disease can be recognized.

Figure 4.20 Measles. (Courtesy of Dr MW McKendrick, Royal Hallamshire Hospital, Sheffield.)

Typical measles

- The **pre-eruptive and catarrhal stage**. This is the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhoea, cough, conjunctival suffusion and the pathognomonic Koplik's spots are present during this stage. Koplik's spots are small, greyish, irregular lesions surrounded by an erythematous base and are found in greatest numbers on the buccal mucous membrane opposite the second molar tooth. They occur a day or two before the onset of the rash.
- The **eruptive or exanthematous stage**. This is characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (Fig. 4.20). At first, the rash is discrete but later it may become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

The most feared complication in an immunocompetent child is acute measles encephalitis, with an incidence of 1/1000 to 1/5000 cases of measles. This is post-infectious, i.e. virus is not present in the brain and the encephalitis presumably arises through an aberrant cross-reaction of the host immune response to infection. Prognosis is poor, with a high mortality (30%) and severe residual damage in survivors.

Measles carries a high mortality in the malnourished and in those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media and gastroenteritis. Less commonly, myocarditis, hepatitis and encephalomyelitis may occur. In those who are malnourished or those with defective cell-mediated immunity, the classical maculopapular rash may not develop and widespread desquamation may occur. The virus also causes the rare condition subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (<18 months of age). Persistence of the virus with reactivation pre-puberty results in accumulation of virus in the brain, progressive mental deterioration and a fatal outcome (see p. 1082).

Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

Diagnosis and treatment

Most cases of measles are diagnosed clinically but detection of measles-specific IgM in blood or oral fluid, or genome or antigen detection from nasopharyngeal aspirates or throat swabs should be used to confirm the diagnosis.

FURTHER READING

Heymann DL, Fine PE, Griffiths UK et al. Measles eradication: past is prologue. *Lancet* 2010; 376: 1719–1720.

Treatment is supportive. Antibiotics are indicated only if secondary bacterial infection occurs.

Prevention

A previous attack of measles confers a high degree of immunity and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated for previously unimmunized children below 3 years of age, during pregnancy and in those with debilitating disease.

Active immunization. Children in the UK are immunized with the combined mumps-measles-rubella (MMR) vaccine (Box 4.6). In developing countries, the first measles vaccination is given at 9 months.

Mumps

Mumps is the result of infection with a paramyxovirus. It is spread by droplet infection, by direct contact or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2–3 days before the onset of the parotitis and for 3 days afterwards.

Clinical features

The incubation period averages 18 days. Although no age is exempt, it is primarily a disease of school-aged children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are nonspecific and include fever, malaise, headache and anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling (Fig. 4.21). These enlarged glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus due to pain is common at this stage. Sub-mandibular gland involvement occurs less frequently.

Complications

CNS involvement is the most common extrasalivary gland manifestation of mumps. Clinical meningitis occurs in 5% of all infected patients and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Figure 4.21 Mumps: a child with a swollen face. (From Chaudhry B, Harvey DR. Mosby's Color Atlas and Text of Paediatrics and Child Health. Edinburgh: Mosby; 2001. ©Elsevier 2001.)

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, oophoritis, myocarditis, mastitis, hepatitis and polyarthritis may also occur.

Diagnosis and treatment

The diagnosis of mumps is on the basis of the clinical features. In doubtful cases, serological demonstration of a mumps-specific IgM response in an acute blood or oral fluid sample is diagnostic. Virus can be isolated in cell culture, or identified by genome or antigen detection assays, from saliva, throat swab, urine and CSF.

Treatment is supportive. Attention should be given to adequate nutrition and mouth care. Analgesics should be used to relieve pain.

Prevention

Active immunization. Children in the UK are immunized with the MMR vaccine (Box 4.6) and the mumps vaccine is given in most developing countries. Vaccination is contraindicated in immunosuppressed individuals, during pregnancy, or in those with severe febrile illnesses.

Respiratory syncytial virus infection

Respiratory syncytial virus (RSV) is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1–3 days a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyperexpansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac, respiratory (including prematurity) or immunodeficiency disease. RSV infection has been associated with the occurrence of sudden infant death syndrome (SIDS). The virus undergoes antigenic drift and, consequently, reinfection occurs throughout life. RSV is occasionally the cause of outbreaks of influenza-like illness or pneumonia in the elderly and in the immunocompromised.

Transfer of infection between children in hospital commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to handwashing and other infection control measures reduces the risk of transmission by staff members.

Diagnosis and treatment

Genome detection or immunofluorescence on nasopharyngeal aspirates, virus culture and serology are the usual ways of confirming the diagnosis.

Treatment is generally supportive, but aerosolized ribavirin can be given to severe cases, particularly those with underlying cardiac or respiratory disease.

Prevention

No vaccine is currently available for RSV but high-risk children (including those with bronchopulmonary dysplasia and congenital heart disease) can be protected against severe disease by monthly administration of either a hyperimmune globulin against RSV, or a humanized monoclonal antibody (palivizumab) during the winter months (see this chapter).

Metapneumovirus

Human metapneumovirus (hMPV) causes approximately 10% of lower respiratory tract infections in infants and young

children. Infection is clinically indistinguishable from that caused by RSV.

Hendra and Nipah viruses

Hendra virus (formerly called equine morbillivirus) and Nipah virus are zoonotic viruses that have caused disease in humans who have been in contact with infected animals (horses and pigs, respectively). The viruses are named after the locations where they were first isolated, Hendra in Australia and Nipah in Malaysia, and both are classified as paramyxoviruses. Hendra virus has caused severe respiratory distress in horses and humans and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999. Treatment of these conditions is largely supportive, although there is some evidence that early treatment with ribavirin may reduce the severity of the diseases.

Coronaviruses

Human coronaviruses were first isolated in the mid-1960s and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In November 2002, an apparently new viral disease occurred in China and this spread rapidly in other parts of the Far East and thence across the world.

This disease, known as 'severe acute respiratory syndrome' (SARS), of which bronchopneumonia is a major feature, is caused by a previously unknown coronavirus (SARS-CoV). Similarity of this virus to coronaviruses isolated from civet cats, raccoons and ferret badgers indicates the likelihood that SARS is a zoonotic disease. Bats are the likely host species for this virus.

The epidemic was finally brought under control in the summer of 2003, by which time there had been >8000 cases with approximately 800 deaths. In 2004 and 2005, two new coronavirus infections of humans were described – NL63 and HKU1. These are associated with upper respiratory tract symptomatology, such as the common cold.

Rhabdoviruses

Rabies

Rabies is a major problem in some countries, with an estimated 55 000 deaths per year worldwide. Established infection is almost invariably fatal. It is caused by a genotype 1, single-stranded RNA virus of the *Lyssavirus* genus. The rabies virus is bullet-shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:

- **Urban rabies** is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- **Sylvan (wild) rabies** is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses and bats.

With the exception of Australia, New Zealand and the Antarctic, human rabies has been reported from all continents. Transmission is usually through the bite of an infected animal. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

Virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the spinal cord and brain. In the CNS the virus again proliferates before spreading to the salivary glands, lungs, kidneys and other organs via the autonomic nerves.

There have been only six recorded cases of survival from clinical rabies.

Clinical features

The incubation period is variable, ranging from a few weeks to several years; on average it is 1–3 months. In general, bites on the head, face and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:

- **Furious rabies** – the classic variety
- **Dumb rabies** – the paralytic variety.

Furious rabies

The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour and paralysis may also occur. Hyperexcitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is due to severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyperreflexia, spasticity and evidence of sympathetic overactivity indicated by pupillary dilatation and diaphoresis.

The patient goes on to develop convulsions, respiratory paralysis and cardiac arrhythmias. Death usually occurs in 10–14 days.

Dumb rabies

Dumb rabies, or paralytic rabies, presents with a symmetrical ascending paralysis resembling the Guillain-Barré syndrome. This variety of rabies commonly occurs after bites from rabid bats.

Diagnosis

The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be isolated using the reverse transcription polymerase chain reaction (RT-PCR). Isolation of viruses from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. The corneal smear test is not recommended as it is unreliable. The classic Negri bodies are detected at post-mortem in 90% of all patients with rabies; these are eosinophilic, cytoplasmic, ovoid bodies, 2–10 nm in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using RT-PCR, immunofluorescence assay (IFA) or tissue culture of the brain.

Treatment

Once the CNS disease is established, therapy is symptomatic, as death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory and cardiovascular support may be necessary.

Drugs such as morphine, diazepam and chlorpromazine should be used liberally in patients who are excitable.

Prevention

Pre-exposure prophylaxis. This is given to individuals with a high risk of contracting rabies, such as laboratory workers,

animal handlers and veterinarians. Three doses (1.0 mL) of human diploid (HDCV) or chick embryo cell vaccine given by deep subcutaneous or intramuscular injection on days 0, 7 and 28 provide effective immunity. A reinforcing dose is given after 12 months and additional reinforcing doses are given every 3–5 years depending on the risk of exposure. Vaccines of nervous-tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and are best avoided if HDCV is available.

Post-exposure prophylaxis. The wound should be cleaned carefully and thoroughly with soap and water and left open. Human rabies immunoglobulin should be given immediately (20 IU/kg); half should be injected around the area of the wound and the other half should be given intramuscularly. Five 1.0 mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7, 14 and 28. Reaction to the vaccine is uncommon.

Control of rabies

Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals for 6 months and no indigenous case of rabies has been reported for many years. The Pet Travel Scheme (PETS) recently introduced enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies and meet the conditions of the scheme. Wild animals in 'at risk' countries must be handled with great care.

Retroviruses

Retroviruses (Table 4.22) are distinguished from other RNA viruses by their ability to replicate through a DNA intermediate using the enzyme reverse transcriptase.

HIV-1 and the related virus, HIV-2, are further classified as lentiviruses ('slow' viruses) because of their slowly progressive clinical effects.

HIV-1 and HIV-2 are discussed on page 173.

HTLV-1 causes adult T-cell leukaemia/lymphoma and tropical spastic paraparesis.

Arenaviruses

Arenaviruses are pleomorphic, round or oval viruses with diameters ranging from 50 to 300 nm. The virion surface has club-shaped projections and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. Arenaviruses are responsible for Lassa fever and also for lymphocytic choriomeningitis, Argentinian and Bolivian haemorrhagic fevers.

Lassa fever

This illness was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa

(Nigeria, Liberia and Sierra Leone). The multimammate rat, *Mastomys natalensis*, is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10–30% of infections are symptomatic.

Clinical features

The incubation period is 7–18 days. The disease is insidious in onset and is characterized by fever, myalgia, severe back-ache, malaise and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis and lymphadenopathy occur in over 50% of patients. In severe cases, epistaxis and gastrointestinal bleeding may occur; hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1–3 weeks and recovery within 1 month of the onset of illness is usual. However, death occurs in 15–20% of hospitalized patients, usually from irreversible hypovolaemic shock.

Diagnosis

The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by genome detection by means of RT-PCR in throat swab, serum or urine.

Treatment

Treatment is supportive. In addition, clinical benefit and reduction in mortality can be achieved with ribavirin therapy, if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. As Lassa fever virus and other causes of haemorrhagic fever (Marburg/Ebola and Congo-Crimean haemorrhagic fever viruses, Table 4.23) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

Lymphocytic choriomeningitis (LCM)

This infection is a zoonosis, the natural reservoir of LCM virus being the house mouse. Infection is characterized by:

Table 4.23 Viral infections associated with haemorrhagic manifestations^a

Flavivirus
Yellow fever (urban and sylvan)
Dengue haemorrhagic fever
Kysanur Forest disease
Omsk haemorrhagic fever

^aHTLV, human T-cell lymphotropic virus.

- Non-nervous-system illness, with fever, malaise, myalgia, headache, arthralgia and vomiting
- Aseptic meningitis in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.

This illness is generally self-limiting and requires no specific treatment.

Filoviruses

Marburg virus disease and Ebola virus disease

These severe, haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar. The diseases are named after Marburg in Germany and the Ebola River region in the Sudan and Zaire where these viruses first appeared. The natural reservoir for these viruses has not been identified and the precise mode of spread from one individual to another has not been elucidated.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. The mortality from Marburg and Ebola has ranged from 25% to 90% and recovery is slow in those who survive.

The illness is characterized by the acute onset of severe headache, severe myalgia and high fever, followed by prostration. On about the fifth day of illness a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and is associated with abdominal cramps and vomiting. Haematemesia, melaena or haemoptysis may occur between the 7th and 16th day. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease, chest pain and a dry cough are prominent symptoms.

Treatment is symptomatic. Convalescent human serum may decrease the severity of the attack.

POSTVIRAL/CHRONIC FATIGUE SYNDROME (see also p. 1162)

Many viral infections have been implicated aetiologically, including EBV, Coxsackie B viruses, echoviruses, CMV and hepatitis A virus. Non-viral causes such as allergy to *Candida* spp. have also been proposed. Only a minority of patients have an identifiable precipitating infectious illness. Reports of identification of an infectious retrovirus, xenotropic murine leukaemia virus-related virus (XMRV), in the peripheral blood of a high percentage of patients with CFS (but not in the blood of healthy controls) in late 2009, generated considerable excitement among both patients and their carers. However, a number of independent investigators have failed to confirm these findings, which remain unproven.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES (TSE OR PRION DISEASES)

Transmissible spongiform encephalopathies are caused by the accumulation in the nervous system of a protein, termed a 'prion', which is an abnormal isoform PrP^{Sc} of a normal, host protein (PrP^C).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly

if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions; thus these agents cannot be considered orthodox viruses and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia, which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are Creutzfeldt–Jakob disease, including the sporadic, familial, iatrogenic and variant forms of the disease, Gerstmann–Straussler–Scheinker syndrome, fatal familial insomnia and kuru.

- **Creutzfeldt–Jakob disease (CJD)** usually occurs sporadically worldwide with an annual incidence of one per million of the population. Although, in most cases, the epidemiology remains obscure, transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin, from dura mater and corneal grafting and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).
- **Variant CJD.** In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE) had gone into the human food chain, led to enhanced surveillance for emergence of the disease in humans. The evidence is convincing, based on transmission studies in mice and on glycosylation patterns of prion proteins, that this has occurred and, to date, there have been approximately 170 confirmed and suspected cases of variant CJD (human BSE) in the UK and 40 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, variant CJD presents with ataxia, dementia, myoclonus and chorea at a mean age of onset of 29 years. The epidemic curve of vCJD in the UK is shown in Figure 4.22.

Figure 4.22 Creutzfeldt–Jakob disease. Deaths of confirmed variant and sporadic cases of CJD (to early Dec. 2010) in the UK. (Courtesy of Professor JW Ironside, Director National CJD Surveillance Unit, University of Edinburgh.)

- **Gerstmann–Straussler–Scheinker syndrome** and **fatal familial insomnia** are rare prion diseases, usually occurring in families with a positive history. The pattern of inheritance is autosomal dominant with some degree of variable penetrance. The gene encoding PrP^C in these families often contains mutations.
- **Kuru** was described and characterized in the Fore highlanders in NE New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished and recent cases had all been exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In the infected host there is no evidence of inflammatory, cytokine or immune reactions. The agent is highly resistant to decontamination and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to γ -irradiation. Autoclaving at a high temperature (134–137°C for 18 min) is used for decontamination of instruments and hypochlorite (20 000 p.p.m. available chlorine) or 1 molar sodium hydroxide are used for liquid disinfection. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

BACTERIAL INFECTIONS

Classification of bacteria

Bacteria are unicellular organisms (prokaryotes), of which only a small fraction are of medical relevance. They have traditionally been classified according to the Gram stain which distinguishes Gram-positive from Gram-negative organisms. Using light microscopy, these can then largely be divided into cocci and bacilli (rods). Some have a spiral appearance (spirochaetes) while others, such as *Clostridium* spp., may contain spores (Table 4.24). The cell wall arrangement of Gram-positive cocci contains a phospholipid bilayer surrounded by peptidoglycan made up of repeating units of *N*-acetylglucosamine and *N*-acetylmuramic acid. By contrast, Gram-negative bacilli possess a second outer lipid bilayer containing protein and lipopolysaccharide (endotoxin). Genetic classification is redefining bacteria in terms of DNA sequence information and has led to the reclassification of several bacterial species.

Bacteria can often be cultured in broth or on solid agar. Those growing in the absence of oxygen are strict anaerobes (e.g. *Bacteroides* spp.), while oxygen-dependent bacteria are known as aerobes (e.g. *Pseudomonas* spp.). Many pathogens can tolerate reduced concentrations of oxygen (e.g. *E. coli*). Some organisms are more demanding in their growth requirements and require special laboratory media (e.g. *Mycoplasma* spp. and *Mycobacterium* spp.); others require more prolonged incubation (e.g. *Brucella* spp.).

Diagnosis and management of bacterial infections

The history and examination usually localizes the infection to a specific organ or body site. A systemic response may accompany such localized disease or, in the case of blood-stream infections, be the primary mode of presentation. The microbiological diagnosis is difficult to establish in most community-managed infections and even in hospital where there is ready access to diagnostic laboratories, only a minority of infections are documented. For these reasons, a clinical approach to bacterial diseases has been adopted.

Skin and soft tissue infection

Superficial infections

Infections of the skin and the soft tissues beneath are common. These are usually fungal (see p. 1200) or bacterial. Although a wide range of bacteria have been recovered from

skin and soft tissue infections (Table 4.25), the majority are caused by the Gram-positive cocci *Staphylococcus aureus* and *Streptococcus pyogenes*.

Staphylococcus aureus

Staphylococci are part of the normal microflora of the human skin and nasopharynx; up to 25% of people are carriers of *S. aureus*, which is the species responsible for the majority of staphylococcal infections. Although soft tissue infections are the most common manifestation of *S. aureus* disease, numerous other sites can be affected (Table 4.6).

The classification of soft tissue infections is complex, because imprecise and overlapping terms are in use. (The commonly encountered infections are described in more detail on page 1195.)

The majority of skin and superficial soft tissue infections are due to bacteria on the skin surface penetrating the dermis or the subcutaneous tissues. Infection can take place via hair follicles, insect bites, cuts and abrasions or skin damaged by superficial fungal infection. Sometimes infection is introduced by an animal bite or a penetrating foreign body; in these cases more unusual organisms may be found. A number of factors predispose to cellulitis and other soft tissue infections (Table 4.26).

Invasive staphylococcal infection is often associated with breaches in the skin, for example due to injecting drug use, iatrogenic cannulation, surgery, or trauma. In clinical situations scrupulous attention to disinfection and hygiene when performing invasive procedures can minimize the risk of infection. Although *S. aureus* is the most common species of staphylococci implicated in catheter-related infections, other normally non-pathogenic species such as *S. epidermidis* (which is often intrinsically resistant to flucloxacillin) may be found. Flucloxacillin remains the first choice in staphylococcal infection when the organism is known to be sensitive, but with the increasing prevalence of methicillin-resistant *S. aureus* (MRSA), other agents are often needed. Other options in uncomplicated cellulitis include clindamycin and clarithromycin, while for more serious infections (or when MRSA is suspected) options include glycopeptides, linezolid and daptomycin.

S. aureus can produce a variety of toxins and virulence factors which affect the type and severity of infection. These include staphylococcal enterotoxin A, superantigenic staphylococcal exotoxins, toxic shock toxin 1 and Panton Valentine leucocidin (PVL). The last of these has been found mainly in community-associated strains of *S. aureus* (both

Meticillin-resistant *Staphylococcus aureus* (MRSA)

S. aureus are commonly resistant to penicillin and isolated resistance to other β -lactam antibiotics such as meticillin (now rarely used) and flucloxacillin has been recognized since the development of the first semisynthetic penicillins in the early 1960s. However, in the last 40 years strains of MRSA with resistance to a much wider range of antibiotics have emerged. In some cases only the glycopeptide antibiotics, vancomycin and teicoplanin, are effective (along with the new agents discussed below) and a few organisms have been isolated with decreased sensitivity even to these.

MRSA and MSSA), rather than in hospital-acquired or epidemic strains. Community-associated PVL-producing MRSA and MSSA are becoming an increasingly common cause of invasive soft tissue and lung infections in some countries (notably the USA), although it is unclear whether PVL itself is directly responsible for the increased virulence.

Vancomycin-insensitive *S. aureus* (VISA) develop because the organism produces a thick cell wall by changing the synthesis of cell wall material. Vancomycin-resistant *S. aureus* (VRSA) acquires resistance by receiving the van A gene from vancomycin-resistant enterococci (see Fig. 4.4).

Apart from the glycopeptides, four other classes of antibiotics are effective against Gram-positive bacteria, including MRSA: these are the streptogramins (e.g. quinupristin with dalbapristin), the oxazolidinones (e.g. linezolid), tigecycline and daptomycin. They should usually be reserved for multi-resistant organisms. Control of the use of antibiotics in hospitals and good infection control policies are vital to prevent the emergence and spread of multiresistant organisms. Scrupulous hygiene on the part of healthcare workers is especially necessary (e.g. handwashing).

MRSA is usually found as a skin commensal, especially in hospitalized patients or nursing home residents. However, it can cause a variety of infections in soft tissues and elsewhere and can cause death. It is particularly associated with surgical wound infections. Eradication of the organism is difficult and people who are known to be colonized should be isolated from those at risk of significant infection. Topical decolonization is often used, but is of limited efficacy. Handwashing is more effective at controlling spread.

Although MRSA is generally regarded as a hospital-associated organism, it is now commonly seen in people away from the hospital setting, both as a colonizer and as a cause of disease. Often the organisms are the typical 'hospital' strains of MRSA and have been acquired directly or indirectly from a healthcare setting (e.g. in workers in care homes). However, there is an increasing prevalence in some countries of true community-associated MRSA (CA-MRSA), with no discernible links to hospital or residential care. These CA-MRSA have different resistance profiles to typical hospital strains (often retaining sensitivity to tetracyclines, clindamycin and co-trimoxazole) and are more likely to produce PVL.

Detection

Culture takes 24 hours. A rapid (2 hour) real-time PCR assay is now available.

Pasteurellosis

Pasteurella multocida is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infections following animal bites. Although the infection initially resembles other forms of cellulitis, there is a greater tendency to spread to deeper tissues, resulting in osteomyelitis, tenosynovitis or septic arthritis. The organism is sensitive to penicillin, but as infections following animal bites are often polymicrobial, co-amoxiclav is a better choice.

Cat-scratch disease

Cat-scratch disease is a zoonosis caused by *Bartonella henselae*. Asymptomatic bacteraemia is relatively common in domestic and especially feral cats and human infection is probably due to direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears 1–2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in the immunocompromised. In these patients, tender cutaneous or subcutaneous nodules are seen (*bacillary angiomatosis*), which may ulcerate. The lymphadenopathy

resolves spontaneously over weeks or months, although surgical drainage of very large suppurating nodes may be necessary. *B. henselae* is sensitive to azithromycin, doxycycline and ciprofloxacin, but drug selection and clinical benefit of treatment is variable according to the primary site of the infection.

Toxin-mediated skin disease

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

Staphylococcal scalded skin syndrome

The scalded skin syndrome is caused by a toxin-secreting strain of *S. aureus*. It principally affects children under the age of 5. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum leading to the formation of large flaccid blisters that shear readily. It is a relatively benign condition and responds to treatment with flucloxacillin.

Toxic shock syndrome (TSS)

TSS is usually due to toxin-secreting staphylococci, but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use in women, this is not always the case. The exotoxin (normally toxic shock syndrome toxin 1, TSST-1) causes cytokine release with abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill and mortality is about 5%. Treatment is mainly supportive, although the organism should be eradicated.

Scarlet fever

See page 117.

Deep soft tissue infections

Infections of the deeper soft tissues are much less common than superficial infections and tend to be more serious. Usually they are related to penetrating injuries (including injecting drug use) or to surgery and the causative organisms relate to the nature of the wound.

Necrotizing fasciitis

Necrotizing fasciitis is a fulminant, rapidly spreading infection associated with widespread tissue destruction (through all tissue planes) and a high mortality. Historically, two forms are described. Type 1, caused by a mixture of aerobic and anaerobic bacteria, is usually seen following abdominal surgery or in diabetics. Type 2, caused by group A streptococci (GAS), arises spontaneously in previously healthy people. Other organisms are now also recognized as causing necrotizing fasciitis, most notably *Vibrio* species (*V. vulnificans*), associated with sea water in the tropics. All types are characterized by severe pain at the site of initial infection, rapidly followed by tissue necrosis. Infection tracks rapidly along the tissue planes, causing spreading erythema, pain and sometimes crepitus. In patients with fever, toxicity and pain which is out of proportion to the skin findings, necrotizing fasciitis should be suspected and must be treated aggressively and promptly with antibiotics and urgent surgical exploration with extensive debridement or amputation if necessary. Laboratory investigations show a high CRP and a very raised white count (often over $25 \times 10^9/L$). Imaging with US/CT may be helpful but should not delay urgent surgical exploration. Multiorgan

Desquamation of the palms.

Necrotizing fasciitis with widespread tissue destruction (following treatment).

failure is common and mortality is high. Confirmed GAS necrotizing fasciitis is treated with high doses of benzylpenicillin and clindamycin; mixed or unknown organism infection is treated with a broad-spectrum combination, which should include metronidazole.

Gas gangrene

Gas gangrene is caused by deep tissue infection with *Clostridium* spp., especially *C. perfringens*, and follows contaminated penetrating injuries. It is historically associated with battlefield wounds, but is also seen in intravenous drug users and following abdominal surgery. The initial infection develops in an area of necrotic tissue caused by the original injury; toxins secreted by the bacteria kill surrounding tissue and enable the anaerobic organism to spread rapidly. Toxins are also responsible for the severe systemic features of gas gangrene. Treatment consists of urgent surgical removal of necrotic tissue and treatment with benzylpenicillin and clindamycin.

Respiratory tract infections

Infections of the respiratory tract are divided into infections of the upper and lower respiratory tract, which are separated by the larynx. In health, the lower respiratory tract is normally sterile owing to a highly efficient defence system (see p. 791). Infections of the upper respiratory tract are particularly common in childhood when they are usually the result of virus infection. The paranasal sinuses and middle ear are contiguous structures and can be involved secondary to viral infections of the nasopharynx. The lower respiratory tract is frequently compromised by smoking, air pollution, aspiration of upper respiratory tract secretions and chronic lung disease, notably chronic obstructive pulmonary disease. Infections of the respiratory tract are defined clinically, sometimes radiologically, as in the case of pneumonia and by appropriate microbiological sampling.

Upper respiratory tract infections

- The common cold (acute coryza) (see p. 808)
- Sinusitis (see p. 1052)
- Rhinitis (see p. 808)
- Pharyngitis (see p. 810).

Scarlet fever

Scarlet fever occurs when the infectious organism (usually a group A streptococcus) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies. Infections may be sporadic or epidemic occurring in residential institutions such as schools, prisons and military establishments.

Clinical features

The incubation period of this relatively mild disease, which mainly affects children, is 2–4 days following a streptococcal infection, usually in the pharynx. Regional lymphadenopathy, fever, rigors, headache and vomiting are present. The rash, which blanches on pressure, usually appears on the second day of illness; it initially occurs on the neck but rapidly becomes punctate, erythematous and generalized. It is typically absent from the face, palms and soles and is prominent in the flexures. The rash usually lasts about 5 days and is followed by extensive desquamation of the skin (Fig. 4.23). The face is flushed, with characteristic circumoral pallor. Early in the disease, the tongue has a white coating through which prominent bright red papillae can be seen ('strawberry

Figure 4.23 Scarlet fever rash, showing desquamation.

tongue'). Later the white coating disappears, leaving a raw-looking, bright red colour ('raspberry tongue'). The patient is infective for 10–21 days after the onset of the rash, unless treated with penicillin.

Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

Diagnosis

The diagnosis is established by the typical clinical features and culture of a throat swab.

Treatment

Treatment is with penicillin V, amoxicillin or clarithromycin for 10 days. It is usually effective in preventing rheumatic fever (see p. 128) and acute glomerulonephritis (see p. 562), which are non-suppurative complications of streptococcal pharyngitis.

Prevention

Chemoprophylaxis with penicillin or clarithromycin should be given in outbreaks.

Diphtheria

Diphtheria (caused by *Corynebacterium diphtheriae*) occurs worldwide. Its incidence in the West has fallen dramatically following widespread active immunization, but has re-emerged in the independent states of the former Soviet Union. Transmission is mainly through air-borne droplet infection. *C. diphtheriae* is a Gram-positive bacillus: only strains which carry the tox+ gene are capable of toxin production.

Clinical features

Diphtheria was formerly a disease of childhood but may affect adults in countries where childhood immunization has been interrupted or uptake is poor. The incubation period is 2–7 days. The manifestations may be regarded as local (due to the membrane) or systemic (due to exotoxin). The presence of a membrane, however, is not essential to the diagnosis. The illness is insidious in onset, but may be complicated by co-infection with other bacteria such as *Strep. pyogenes*.

Nasal diphtheria is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

Pharyngeal diphtheria is associated with the greatest toxicity and is characterized by marked tonsillar and pharyngeal inflammation and the presence of a membrane. The tough greyish yellow membrane is formed by fibrin, bacteria,

epithelial cells, mononuclear cells and polymorphs and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called 'bull-neck'.

Laryngeal diphtheria is usually a result of extension of the membrane from the pharynx. A husky voice, a brassy cough and later dyspnoea and cyanosis due to respiratory obstruction are common features.

Clinically evident myocarditis occurs, often weeks later, in patients with pharyngeal or laryngeal diphtheria. Acute circulatory failure due to myocarditis may occur in convalescent individuals around the 10th day of illness and is usually fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies, paraesthesiae, polyneuropathy or rarely encephalitis).

Cutaneous diphtheria is uncommon but seen in association with burns and in individuals with poor personal hygiene. Typically the ulcer is punched-out with undermined edges and is covered with a greyish white to brownish adherent membrane. Constitutional symptoms are uncommon.

Diagnosis

This must be made on clinical grounds since therapy is usually urgent: the mortality rate is about 10%. It is confirmed by bacterial culture and toxin studies.

Treatment

The patient should be isolated. Antitoxin therapy is the only specific treatment. It must be given promptly to prevent further fixation of toxin to tissue receptors, since fixed toxin is not neutralized by antitoxin. Depending on the severity, 20 000–100 000 units of horse-serum antitoxin should be administered intramuscularly after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in a very severe case. There is a risk of acute anaphylaxis after antitoxin administration and of serum sickness 2–3 weeks later (Box 4.8). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production. Benzylpenicillin 1.2 g four times daily is given for 1 week.

The cardiac and neurological complications need intensive therapy. Recovery and rehabilitation can take many weeks.

Prevention

Diphtheria is prevented by active immunization in childhood (see this chapter). Booster doses should be given to those travelling to endemic areas if more than 10 years has elapsed following their primary course of immunization. All contacts of the patient should have throat swabs sent for culture; those with a positive result should be treated with penicillin or a macrolide and given active immunization or a booster dose of diphtheria toxoid.

Box 4.8 Antitoxin administration

- Many antitoxins are heterologous and therefore dangerous.
- Hypersensitivity reactions are common.

Prior to treatment

- Question patient about:
 - allergic conditions (e.g. asthma, hay fever)
 - previous antitoxin administration.
- Read instructions on antitoxin package carefully.
- Always give a subcutaneous test dose.
- Have adrenaline (epinephrine) available.

Pertussis (whooping cough)

Pertussis occurs worldwide. Humans are both the natural hosts and reservoirs of infection. The disease is caused by *Bordetella pertussis* which is a Gram-negative coccobacillus. *B. parapertussis* and *B. bronchiseptica* produce milder infections. Pertussis is highly contagious and is spread by droplet infection. In its early stages it is indistinguishable from other types of upper respiratory tract infection. Epidemic disease occurred in the UK when the safety of the whooping cough vaccine was questioned; currently, uptake exceeds 95% and the disease is uncommon.

Clinical features

The incubation period is 7–10 days. It is a disease of childhood, with 90% of cases occurring below 5 years of age. However, no age is exempt, although in adults it may be unsuspected.

During the catarrhal stage, the patient is highly infectious and cultures from respiratory secretions are positive in over 90% of patients. Malaise, anorexia, mucoid rhinorrhoea and conjunctivitis are present. The paroxysmal stage, so called because of the characteristic paroxysms of coughing, begins about 1 week later. Paroxysms with the classic inspiratory whoop are seen only in younger individuals in whom the lumen of the respiratory tract is compromised by mucus secretion and mucosal oedema. These paroxysms usually terminate in vomiting. Conjunctival suffusion and petechiae and ulceration of the frenulum of the tongue are usual. Lymphocytosis due to the elaboration of a lymphocyte-promoting factor by *B. pertussis* is characteristic. This stage lasts approximately 2 weeks and may be associated with several complications, including pneumonia, atelectasis, rectal prolapse and inguinal hernia. Cerebral anoxia may occur, especially in younger children, resulting in convulsions. Bronchiectasis is a rare sequel.

Diagnosis

The diagnosis is suggested clinically by the characteristic whoop and a history of contact with an infected individual. It is confirmed by culturing the organism from a nasopharyngeal swab. PCR assays are also available.

Treatment

If the disease is recognized in the catarrhal stage, macrolides will abort or decrease the severity of the infection (although resistance to these agents has been reported in the USA). Azithromycin for 5 days is frequently used. In the paroxysmal stage, antibiotics have little role to play in altering the course of the illness.

Prevention and control

Affected individuals should be isolated to prevent contact with others, e.g. in hostels and boarding schools. Pertussis is an easily preventable disease and effective active immunization is available (Box 4.6). Convulsions and encephalopathy have been reported as rare complications of vaccination but they are probably less frequent than after whooping cough itself. Any exposed susceptible infant should receive prophylactic clarithromycin.

Acute epiglottitis (see p. 811)

This has been virtually eliminated among children in those countries which have introduced *Haemophilus influenzae* vaccine, as in the UK. Occasionally, infections are seen in adults. The clinical features are described in Chapter 15.

Acute laryngotracheobronchitis (CROUP)

See page 811.

Influenza

See page 811.

Lower respiratory tract infections

Pneumonia: community-acquired (see p. 833); hospital-acquired (see p. 838); in immunocompromised persons (see p. 118).

Psittacosis (ornithosis)

Although originally thought to be limited to the psittacine birds (parrots, parakeets and macaws), it is known that the disease is widely spread among many species of birds, including pigeons, turkeys, ducks and chickens (hence the broader term 'ornithosis'). Human infection is related to exposure to infected birds and is therefore a true zoonosis. The causative organism, *Chlamydia psittaci*, is excreted in avian secretions; it can be isolated for prolonged periods from birds who have apparently recovered from infection. The organism gains entry to the human host by inhalation. (For *Clinical features and treatment*, see page 837.)

Acinetobacter infection

This Gram-negative coccobacillus is becoming increasingly prominent in hospital-acquired infections, particularly as a cause of ventilator-associated pneumonia (see p. 894) and vascular catheter infections. It is a cause of community-acquired infections in tropical countries and is associated with wars and natural disasters. The organism is resistant to many antibiotics, including carbapenems. Polymyxin and tigecycline are being used but resistance is still a problem.

Other respiratory infections

Chlamydia pneumoniae causes a relatively mild pneumonia in young adults, clinically resembling infection caused by *Mycoplasma pneumoniae*. Diagnosis can be confirmed by specific IgM serology. Treatment is with clarithromycin 500 mg 12-hourly, tetracycline 500 mg every 6–8 hours or a fluoroquinolone (see also p. 836).

Other chlamydial infections include trachoma (see p. 133), lymphogranuloma venereum (see p. 165) and other genital infections.

Legionnaires' disease. This is caused by *Legionella pneumophila* and other *Legionella* spp. It is described on page 836.

Lung abscess. See page 838.

Tuberculosis. See page 839.

Gastrointestinal infections**Gastroenteritis**

The most common form of acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, three to six bouts of severe diarrhoea every year. Although oral rehydration programmes have cut the death toll significantly, up to 2 million people die every year as a direct result of diarrhoeal disease. In the western world, diarrhoea is both less common and less likely to cause death. However, it remains a major cause of morbidity, especially in the elderly. Other groups who are at increased risk of infectious diarrhoea include travellers to developing countries, men who have sex with men (MSM) and infants in day-care facilities. Viral gastroenteritis (see p. 104) is a common cause of diarrhoea and vomiting in young children, but is rarely seen in adults, other than in the context of common source outbreaks, usually due to noroviruses. Protozoal and helminthic gut infections (see p. 150) are rare in the West but relatively common in developing countries. The most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Mechanisms

Bacteria can cause diarrhoea in three different ways (Table 4.27). Some species may employ more than one of these methods.

Mucosal adherence

Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa. A number of different molecular adhesion mechanisms have been elaborated, e.g. adhesions at the tip of the pili or fimbriae which protrude

Cytotoxin	Damage to mucosa	Dysentery	

from the bacterial surface aid adhesion. For some pathogens, this is merely the prelude to invasion or toxin production but others such as enteropathogenic *Escherichia coli* (EPEC) cause attachment-effacement mucosal lesions on electron microscopy (EM) and produce a secretory diarrhoea directly as a result of adherence. *Enterobacteriaceae* *E. coli* (EAggEC) adhere in an aggregative pattern with the bacteria clumping on the cell surface and its toxin causes persistent diarrhoea in people in developing countries. Diffusely adhering *E. coli* (DAEC) adheres in a uniform manner and may also cause diarrhoea seen in children and in developing countries.

E. coli O104:H4, which was responsible for the outbreak of gastroenteritis in Germany in 2011, has two different diarrhoea-causing *E. coli* pathotypes: typical enteroaggregative *E. coli* and Shiga-toxin-producing *E. coli*.

Mucosal invasion

Invasive pathogens such as *Shigella* spp., enteroinvasive *E. coli* (EIEC) and *Campylobacter* spp. penetrate into the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of 'invasins', which disrupt the host cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry, which also causes the typical symptoms of dysentery: low-volume bloody diarrhoea, with abdominal pain.

Toxin production

Gastroenteritis can be caused by different types of bacterial toxins (see Fig. 4.3):

- **Enterotoxins**, produced by the bacteria adhering to the intestinal epithelium, induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea, without physically damaging the mucosa, e.g. cholera, enterotoxigenic *E. coli* (ETEC). Some enterotoxins preformed in the food primarily cause vomiting, e.g. *Staph. aureus* and *Bacillus cereus*. A typical example of this is 'fried rice poisoning', in which *B. cereus* toxin is present in cooked rice left standing overnight at room temperature.
- **Cytotoxins** damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g. *E. coli* O157).

Clinical syndromes

Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: *watery diarrhoea* (usually due to enterotoxins or adherence) and *dysentery* (usually due to mucosal invasion and damage) (Box 4.9). With some pathogens such as *Campylobacter jejuni* there may be overlap between the two syndromes.

Management

See page 118.

Salmonella

Gastroenteritis can be caused by many of the numerous serotypes of *Salmonella* (all of which are members of a single species, *S. choleraesuis*), but the most commonly implicated are *S. enteritidis* and *S. typhimurium*. These organisms, which are found all over the world, are commensals in the bowels of livestock (especially poultry) and in the oviducts of chicken (where the eggs can become infected). They are usually transmitted to man in contaminated foodstuffs and water.

Salmonellae can affect both the large and small bowel and induce diarrhoea both by production of enterotoxins and by

Box 4.9 Bacterial causes of watery diarrhoea and dysentery

Watery diarrhoea

- *Yersinia enterocolitica*
- *Vibrio parahaemolyticus*
- *Clostridium difficile*

epithelial invasion. The typical symptoms commence abruptly 12–48 h after infection and consist of nausea, cramping abdominal pain, diarrhoea and sometimes fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3–6 days, although the organism may persist in the faeces for several weeks. Bacteraemia occurs in 1–4% of cases and is more common in the elderly and the immunosuppressed. Occasionally bacteraemia is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. In healthy adults *salmonella* gastroenteritis is usually a relatively minor illness, but young children and the elderly are at risk of significant dehydration.

Specific diagnosis is made by culturing the organism from blood or faeces, but management is usually empirical. Antibiotic therapy (ciprofloxacin 500 mg twice daily) may decrease the duration and severity of symptoms, but is rarely warranted (see Box 4.11).

Campylobacter jejuni

C. jejuni is also a zoonotic infection, existing as a bowel commensal in many species of livestock, e.g. poultry and cattle. It is found worldwide and is a common cause of childhood gastroenteritis in developing countries. Adults in these countries may be tolerant of the organism, excreting it asymptotically. In the West, it is a common cause of sporadic food-borne outbreaks of diarrhoea (with about 450 000 cases per year in the UK). The commonest sources are undercooked meat (especially beefburgers and chicken) and contaminated milk products.

Like *salmonella*, *campylobacter* can affect the large and small bowel and can cause a wide variety of symptoms. The incubation period is usually 2–4 days, after which there is an abrupt onset of nausea, diarrhoea and abdominal cramps. The diarrhoea is usually profuse and watery, but an invasive haemorrhagic colitis is sometimes seen. Bacteraemia is very rare and infection is usually self-limiting in 3–5 days. Diagnosis is made from stool cultures. Quinolone resistance is now widespread (30% in the UK) and if symptoms are severe azithromycin 500 mg once daily is the drug of choice (see Box 4.11).

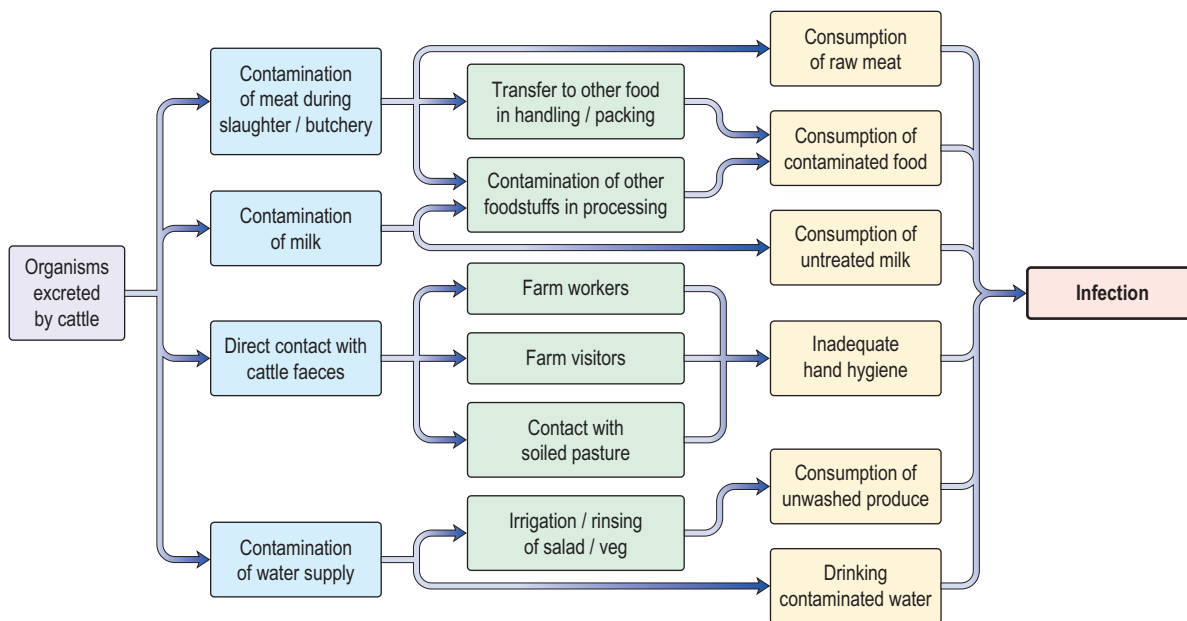

Figure 4.24 Routes of human infection with *E. coli* O157.

Shigella

Shigellae are enteroinvasive bacteria, which cause classical bacillary dysentery. The principal species causing gastroenteritis are *S. dysenteriae*, *S. flexneri* and *S. sonnei*, which are found with varying prevalence in different parts of the world. All cause a similar syndrome, as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelium. Although shigellae are found worldwide, transmission is strongly associated with poor hygiene. The organism is spread from person to person and only small numbers need to be ingested to cause illness (<200, compared with 10^4 for *campylobacter* and $>10^5$ for *salmonella*). Bacillary dysentery is far more prevalent in the developing world, where the main burden falls on children.

Symptoms start 24–48 h after ingestion and typically consist of frequent small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas, but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7–10 days, but in children in developing countries the mortality may be as high as 20%. Antibiotic treatment decreases the severity and duration of diarrhoea, reduces mortality in children and possibly reduces the risk of further transmission (see Box 4.11). Resistance to antibiotics is widespread and wherever possible, treatment should be based on known local sensitivity patterns. In some areas, amoxicillin or cotrimoxazole may still be effective, but in many places, ciprofloxacin is needed (nalidixic acid is no longer recommended due to increasing resistance).

Enteroinvasive *Escherichia coli* (EIEC)

This causes an illness indistinguishable from shigellosis. Definitive diagnosis is made by stool culture, but most cases are probably treated empirically as shigellosis.

Enterohaemorrhagic *Escherichia coli* (EHEC)

EHEC (usually serotype O157: H7 and also known as verotoxin-producing *E. coli*, or VTEC) is a well recognized cause of gastroenteritis in man. It is a zoonosis usually associated with cattle and there have been a number of major outbreaks

(notably in Scotland and Japan) associated with contaminated food. A variety of modes of transmission have been reported and EHEC is a paradigm for all enteric livestock-associated zoonoses (Fig. 4.24). EHEC secretes a toxin (Shiga-like toxin 1) which affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12–48 h it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms the patient may develop thrombotic thrombocytopenic purpura (see p. 125) or haemolytic uraemic syndrome (HUS, p. 589). This is more common in children and may lead to permanent renal damage or death. Non-O157 serotypes are of increasing concern. Between May and June 2011, the largest ever recorded outbreak of Shiga toxin-producing *E. coli* (STEC) causing HUS was recorded in Germany. The outbreak was caused by the O104 serotype and over 2000 people were affected. High rates of HUS were observed in adults not in the typical 'at risk' age range. The increased virulence of this strain is possibly due to it having two different pathotypes (p. 120). Treatment is mainly supportive: there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release and should be avoided.

Enterotoxigenic *Escherichia coli* (ETEC)

ETEC produce both heat-labile and heat-stable enterotoxins, which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food and water. The organism is common in developing countries and is a major cause of travellers' diarrhoea (see below).

Vibrio

Cholera, due to *Vibrio cholerae*, is the prototypic pure enterotoxigenic diarrhoea: it is described on page 133.

Vibrio parahaemolyticus causes acute watery diarrhoea after eating raw fish or shellfish that has been kept for several hours without refrigeration. Explosive diarrhoea, abdominal cramps and vomiting occurs with a fever in 50%. It is self-limiting, lasting up to 10 days.

Pennington H. *Escherichia coli* O157. *Lancet* 2010; 376: 1428–1435.

Yersiniosis

Yersinia enterocolitica infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise either via contaminated food products, e.g. pork, or from direct animal contact. *Y. enterocolitica* can cause a range of gastroenteric symptoms including watery diarrhoea, dysentery and mesenteric adenitis. The illness is usually self-limiting, but ciprofloxacin may shorten the duration. *Y. pseudotuberculosis* is a much less common human pathogen: it causes mesenteric adenitis and terminal ileitis.

Staphylococcus aureus

Some strains of *S. aureus* can produce a heat-stable toxin (enterotoxin B), which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne gastroenteritis in Europe and the USA, outbreaks usually occurring as a result of poor food hygiene. Because the toxin is preformed in the contaminated food, onset of symptoms is rapid, often within 2–4 hours of consumption. There is violent vomiting, followed within hours by profuse watery diarrhoea. Symptoms have usually subsided within 24 hours.

Bacillus cereus

B. cereus produces two toxins. One produces watery diarrhoea up to 12 hours after ingesting the organism. The other toxin is preformed in food and causes severe vomiting.

Clostridial infections

Clostridium difficile causes watery diarrhoea, colitis and pseudomembranous colitis. It is a Gram-positive, anaerobic, spore-forming bacillus and is found as part of the normal bowel flora in 3–5% of the population and even more commonly (up to 20%) in hospitalized people.

Pathogenesis. *C. difficile* produces two toxins: toxin A is an enterotoxin while toxin B is cytotoxic and causes bloody diarrhoea. It causes illness either after other bowel commensals have been eliminated by antibiotic therapy or in debilitated patients who have not been on antibiotics. Almost all antibiotics have been implicated but a recent increase has been attributed in part to the overuse of quinolones (e.g. ciprofloxacin). Hospital-acquired infections remain common, partly due to increased person-to-person spread and from fomites. In recent years new strains of *C. difficile* with greater capacity for toxin production have been reported (e.g. the ribotype NAP1/BI/027). There have been a number of hospital outbreaks with a high mortality.

Clinical features. *C. difficile*-associated diarrhoea (CDAD) can begin anything from 2 days to some months after taking antibiotics. Elderly hospitalized patients are most frequently affected. It is unclear as to why some carriers remain asymptomatic. Symptoms can range from mild diarrhoea to profuse, watery, haemorrhagic colitis, along with lower abdominal pain. The colonic mucosa is inflamed and ulcerated and can be covered by an adherent membrane-like material (pseudomembranous colitis). The disease is usually more severe in the elderly and can cause intractable diarrhoea, leading to toxic megacolon and death. Markers of severity include temperature $>38.5^{\circ}\text{C}$, WCC $>15 \times 10^9$, serum creatinine $>50\%$ above baseline, raised serum lactate, and severe abdominal pain.

Diagnosis is made by detecting A or B toxins in the stools by ELISA or PCR techniques.

Treatment is with metronidazole 400 mg three times daily (mild or moderate disease) or oral vancomycin 125–250 mg four times daily (in more severe or relapsing cases).

Fidaxomicin 200 mg is also effective. Causative antibiotics should be discontinued if possible.

Prevention. Infection control relies on:

- Responsible use of antibiotics
- Hygiene, which should involve all health workers, as well as patients and relatives. Washing hands thoroughly using soap and water is essential as alcohol disinfectants do not kill spores
- Hospital cleaning of surfaces should be performed regularly to try and reduce transmission from fomites
- Isolation of patients with *C. difficile*.

Clostridium perfringens infection is due to inadequately cooked food, usually meat or poultry allowed to cool for a long time, during which the spores germinate. The ingested organism produces an enterotoxin causing watery diarrhoea with severe abdominal pain, usually without vomiting.

Travellers' diarrhoea

Travellers' diarrhoea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country travelling in a developing nation. Infection is usually food- or water-borne, and younger travellers are most often affected (probably reflecting behaviour patterns). Reported attack rates vary from country to country, but approach 50% for a 2-week stay in many tropical countries. The disease is usually benign and self-limiting: treatment with quinolone antibiotics may hasten recovery but is not normally necessary. Prophylactic antibiotic therapy may also be effective for short stays, but should not be used routinely. The common causative organisms are listed in Table 4.28.

Management of acute gastroenteritis

In children, untreated diarrhoea has a high mortality due to dehydration, especially in hot climates. Death and serious morbidity are less common in adults but still occur, particularly in developing countries and in the elderly. The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (ORS): antibiotics have a subsidiary role in some cases (Fig. 4.25; Boxes 4.10 and 4.11). The use and formulation of ORS are discussed under cholera on page 134. It should also be remembered that other diseases, notably urinary tract infections and chest infections in the elderly and malaria at any age, can present with acute diarrhoea.

Food poisoning

Food poisoning is a legally notifiable disease in England and Wales and is defined as 'any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water'. Not all cases of gastroenteritis are food

Table 4.28 Common identified causes of travellers' diarrhoea (TD)^a

Organism	Frequency (varies from country to country)
ETEC	30–70%
<i>Shigella</i> spp.	0–15%
<i>Salmonella</i> spp.	0–10%
<i>Campylobacter</i> spp.	0–15%

poisoning, as the pathogens are not always food- or water-borne. Common bacterial causes of food poisoning are listed in Table 4.29. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Table 4.30). Illnesses such as botulism (see p. 125) are also classified as food poisoning, even although they do not primarily cause gastroenteritis. (Listeriosis is described on page 129.)

The increase in reported food poisoning in developed countries is at least in part due to changes in the production and distribution of food. Livestock raised and slaughtered under modern intensive farming conditions is frequently contaminated with *salmonella* or *campylobacter*. However, the main problem is not at this stage. Only 0.02–0.1% of the eggs from a flock of chickens infected with *S. enteritidis* will be affected and then only at a level of less than 20 cells per egg – harmless to most healthy individuals. It is flaws in the processing, storage and distribution of food products which allow massive amplification of the infection, resulting in extensive contamination. The internationalization of the food supply encourages widespread and distant transmission of the resulting infections. Kitchen hygiene with careful separation of meat products from salads, along

with using the correct temperature for cooking meat are necessary.

Other preventative measures include culling and vaccination of chicken.

Enteric fever (see p. 134)

Other gastrointestinal infections

Gastric infection with *Helicobacter pylori* is discussed on page 248, Whipple's disease on page 268 and bacterial peritonitis on page 300.

Infections of the cardiovascular system

- Infective endocarditis (see p. 751).

Infections of the nervous system

The central and peripheral nervous systems can be affected by a variety of microorganisms including bacteria, viruses (see p. 144) and protozoa (see p. 1128), which cause disease by direct invasion or via toxins. The nervous system is also vulnerable to prion disease (see p. 168 and p. 1126).

Box 4.11 Antibiotics in adult acute bacterial gastroenteritis

Condition	Indications	Drug of choice	Other drugs	Benefits
Dysentery Suspected or confirmed shigellosis	Most patients	Ciprofloxacin 500 mg twice daily	Ampicillin 500 mg four times daily Azithromycin 500 mg once daily Co-trimoxazole 960 mg twice daily	Relieve symptoms Shorten illness Reduce mortality in children Decrease transmission
Cholera	All patients	Ciprofloxacin 500 mg twice daily	Tetracycline 250 mg four times daily Azithromycin 1 g single dose Doxycycline 300 mg single dose	Relieve symptoms Shorten illness Decrease transmission
Empirical therapy of watery diarrhoea	Severe symptoms Prolonged illness Elderly patients Immunosuppressed	Ciprofloxacin 500 mg twice daily	Azithromycin 500 mg once daily Co-trimoxazole	Relieve symptoms Shorten illness May decrease complications
Travellers' diarrhoea	Rarely used	Ciprofloxacin 500 mg twice daily	Co-trimoxazole 960 mg twice daily	Relieve symptoms Shorten illness
Treatment of confirmed <i>Salmonella</i>	Symptoms not improving (rarely needed)	Ciprofloxacin 500 mg twice daily	Azithromycin 500 mg once daily	May shorten illness
Treatment of confirmed <i>Campylobacter</i>	Symptoms not improving (rarely needed)	Azithromycin 500 mg once daily	Co-trimoxazole 960 mg twice daily	May shorten illness
<i>Clostridium difficile</i>	Most cases (unless symptoms resolved)	Metronidazole 400 mg three times daily	Vancomycin 125–250 mg four times daily Fidamoxacin 200 mg twice daily	Relieve symptoms Shorten illness Phase III study

Table 4.29 Bacterial causes of food poisoning

Organism	Source/vehicles	Incubation period	Symptoms	Diagnosis	Recovery
<i>Staphylococcus aureus</i>	Man – contaminated food and water	2–4 h	Diarrhoea, vomiting and dehydration	Culture organism in vomitus or remaining food	<24 h
<i>E. coli</i> (ETEC)	Salads, water, ice	24 h	Watery diarrhoea	Stool culture	1–4 days
<i>E. coli</i> O157 : H7	Cattle – contaminated foodstuffs	12–48 h	Watery diarrhoea ± haemorrhagic colitis, HUS	Stool culture	10–12 days
<i>Yersinia enterocolitica</i>	Milk, pork	2–14 h	Abdominal pain, vomiting, diarrhoea	Stool culture	2–30 days
<i>Bacillus cereus</i>	Environment – rice, ice cream, chicken	1–6 h 6–14 h	Vomiting Diarrhoea	Culture organism in faeces and food	Rapid
<i>Clostridium perfringens</i>	Environment – contaminated food	8–22 h	Watery diarrhoea and cramping pain	Culture organism in faeces and food	2–3 days
<i>Listeria monocytogenes</i>	Environment – milk, raw vegetables, dairy products, unpasteurized cheese	Variable	Colic, diarrhoea and vomiting	Stool culture	Variable
<i>Vibrio parahaemolyticus</i>	Seafood	2–48 h	Diarrhoea, vomiting	Stool, food	2–10 days
<i>Clostridium botulinum</i>	Environment – bottled or canned food	18–24 h	Brief diarrhoea and paralysis due to neuromuscular blockade	Demonstrate toxin in food or faeces	10–14 days
<i>Salmonella</i> spp.	Cattle and poultry – eggs, meat	12–48 h	Abrupt diarrhoea, fever and vomiting	Stool culture	Usually 3–6 days, but may be up to 2 weeks
<i>Campylobacter jejuni</i>	Cattle and poultry – meat, milk	48–96 h	Diarrhoea ± blood, fever, malaise and abdominal pain	Stool culture	3–5 days
<i>Shigella</i> spp.	Man – contaminated food and water	24–48 h	Acute watery, bloody diarrhoea	Stool culture	7–10 days
HUS, haemolytic uraemic syndrome.					

Table 4.30 Organic toxins causing food poisoning (see p. 924)

Toxin	Source	Illness
Scombrototoxin	Tuna, mackerel	Histamine fish poisoning
Ciguatera toxin	Barracuda, snapper	Ciguatera (diarrhoea and paraesthesia)
Dinoflagellate plankton toxin	Shellfish	Neurotoxic shellfish poisoning
Haemagglutinins	Inadequately prepared dried kidney beans	Diarrhoea and vomiting
Unknown	Buffalo fish	Haff disease (toxic rhabdomyolysis)
Phallotoxins, amatoxins	Mushrooms	Various

Bacterial meningitis

The most common bacterial disease affecting the central nervous system is acute meningitis (see p. 1126), which causes about 175 000 deaths per year, predominantly in the developing world. Epidemic meningitis due to *Neisseria meningitidis* (usually group A) is common in a broad belt across sub-Saharan Africa and is also seen in parts of Asia. In Europe and North America, bacterial meningitis is usually sporadic, with serogroup B predominating. A conjugate vaccine for serogroup C meningococcus has resulted in a fall in the number of cases of C meningitis in those countries, where it is now part of the childhood immunization schedule.

Streptococcus pneumoniae is the other major cause throughout the world, while tuberculous meningitis (see p. 1128) is common in sub-Saharan Africa and parts of Asia.

Haemophilus influenzae type b (Hib) was once a common cause of meningitis in children, but since an effective vaccine has been available, serious *H. influenzae* infections have become rare in countries that have also instituted immunization programmes, but invasive *H. influenzae* infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, *Listeria monocytogenes* (see p. 150), *Staph. aureus* and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immunocompromising condition, or with a cerebrospinal fluid leak.

Cerebral abscess

This is covered on page 1130.

Toxin-mediated infections

Botulism

Clostridium botulinum is a common environmental organism that produces spores which can survive heating to 100°C. It causes illness by contaminating canned or bottled foodstuff, in which the anaerobic organism can multiply and elaborate a neurotoxin. After ingestion, the toxin causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18–24 h after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical and is confirmed by detection of toxin in faeces or in the contaminated food. Treatment is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high and it should only be used in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality from botulism is high, but patients who survive the acute paralysis can make a full recovery.

Botulism may also follow the contamination of wounds, street heroin injection contaminated with *C. botulinum* and in infants botulism may be related to bowel colonization by the organism.

Tetanus

Tetanus is also due to a toxin-secreting clostridium: *C. tetani*. The organism is found in soil and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. It has also complicated intravenous drug use. In developing countries, neonatal tetanus follows contamination of the umbilical stump, often after dressing the area with dung.

The organism is not invasive and clinical manifestations of the disease are due to the potent neurotoxin, tetanospasmin. Tetanospasmin acts on both the α and δ motor systems at synapses, resulting in disinhibition. It also produces neuromuscular blockade and skeletal muscle spasm and acts on the sympathetic nervous system. The end result is marked flexor muscle spasm and autonomic dysfunction.

Clinical features

The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) due to masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as risus sardonicus. If the disease is severe, painful reflex spasms develop, usually within 24–72 h of the initial symptoms. The interval between the first symptom and the first spasm is referred to as the 'onset time'. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient, or by light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention respectively and there is arching of the neck and back muscles (opisthotonus). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include short incubation period, short onset time and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery usually occurs.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of *C. tetani* is the middle ear. Cranial nerve abnormalities, particularly of the seventh nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is usually due to infection of the umbilical stump. Failure to thrive, poor sucking, grimacing and irritability are followed by the rapid development of intense

rigidity and spasms. Mortality approaches 100%. One aim of the WHO Expanded Programme on Immunization (EPI) is to eliminate this condition by immunizing all women of child-bearing age, providing clean delivery facilities and strengthening surveillance in high-risk areas.

Diagnosis

Few diseases resemble tetanus in its fully developed form and the diagnosis is therefore usually clinical. Rarely, *C. tetani* is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis and tetany can occasionally mimic tetanus.

Management

Suspected tetanus. Any wound must be cleaned and debrided if necessary, to remove the source of toxin. Human tetanus immunoglobulin 250 units should be given along with an intramuscular injection of tetanus toxoid. If the patient is already protected a single booster dose of the toxoid is given; otherwise the full three-dose course of adsorbed vaccine is given (see below).

Established tetanus. Management is supportive medical and nursing care. Improvement in this area has contributed more than any other single measure to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasms and sedate the patient; if the airway is compromised intubation and mechanical ventilation may be necessary. Magnesium sulphate infusion decreases the need for antispasmodics.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole is the drug of choice, although penicillin and cephalosporins are also effective. Human tetanus immunoglobulin (HTIG) 500 IU should be given by intramuscular injection to neutralize any circulating toxin. If HTIG is not available, immune equine tetanus immunoglobulin 10 000 IU should be given intramuscularly: this is probably as effective as HTIG, but there is a high incidence of severe allergic reactions. If the patient recovers active immunization should be instituted, as immunity following tetanus is incomplete.

Prevention

Tetanus is an eminently preventable disease and all persons should be immunized regardless of age. Active immunization with the alum-adsorbed toxoid should be given. Subsequent boosters are recommended at 10-year intervals for those at risk. Infant immunization schedules in all countries include tetanus (Box 4.6). Protection by passive immunization with either the equine or human antitetanus immunoglobulin is short-lived, lasting only about 2 weeks.

Systemic/multisystem infections

Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances such as altered host immunity, infections which are normally circumscribed may become systemic. This section describes those infections which commonly cause multisystem disease in an immunocompetent host.

Bacteraemia and sepsis syndrome

(see also Ch. 16)

Bacteraemia, the transient presence of organisms in the blood, can occur in healthy people without causing symptoms. It can follow surgery, dental treatment and even tooth-brushing. Bacteraemia can also occur from the bowel or bladder, especially in the presence of local inflammation. Unless a site of metastatic infection is established (such as the heart valves), most organisms are rapidly cleared from the blood.

Sepsis is the term used to describe the signs and symptoms of a systemic inflammatory response syndrome (SIRS) to a localized primary site of infection. Viral, bacterial, fungal and parasitic disease can all trigger the sepsis syndrome.

SIRS is not unique to infection and may complicate a variety of events and conditions such as trauma, chronic inflammatory diseases and malignancy (e.g. lymphoma).

Severe sepsis. This is the presence of the sepsis syndrome (presence of either a positive blood culture or clinical features of fever, tachypnoea, tachycardia, suspected infection), complicated by organ dysfunction, hypotension or hypoperfusion and manifested by low blood pressure, oliguria, hypoxia, acute confusion and lactic acidosis.

Septic shock is defined as the sepsis syndrome plus organ dysfunction and hypotension unresponsive to adequate fluid replacement. Mortality rates often exceed 50%.

Patients presenting with symptoms and signs suggesting sepsis syndrome should be examined for evidence of a source: common sites of infection and responsible organisms are listed in Tables 4.31 and 4.32. Because of the potential to progress to severe sepsis, treatment with antibiotics should usually be started empirically as soon as appropriate cultures have been taken. The choice of agent is governed by the likely pathogen and many hospitals will have local guidelines for the empiric treatment of sepsis. If there are no clues, a broad-spectrum regimen should be used, e.g. piperacillin/tazobactam plus gentamicin, cefotaxime (± metronidazole) or meropenem. In areas where MRSA is prevalent, vancomycin or teicoplanin should be added to this

Table 4.31 Common causes of sepsis in a previously healthy adult

Site of origin	Usual pathogen(s)
Skin	<i>Staphylococcus aureus</i> and other Gram-positive cocci
Urinary tract	<i>Escherichia coli</i> and other aerobic Gram-negative rods
Respiratory tract	<i>Streptococcus pneumoniae</i>
Gall bladder or bowel	<i>Enterococcus faecalis</i> , <i>E. coli</i> and other Gram-negative rods, <i>Bacteroides fragilis</i>
Pelvic organs	<i>Neisseria gonorrhoeae</i> , anaerobes

Table 4.32 Causes of sepsis in hospitalized patients

Clinical problem	Usual pathogen(s)
Urinary catheter	<i>Escherichia coli</i> , <i>Klebsiella</i> spp., <i>Proteus</i> spp., <i>Serratia</i> spp., <i>Pseudomonas</i> spp.
Intravenous catheter	<i>Staphylococcus aureus</i> , <i>Staph. epidermidis</i> , <i>Klebsiella</i> spp., <i>Pseudomonas</i> spp., <i>Candida albicans</i>
Post-surgery:	
Wound infection	<i>Staph. aureus</i> , <i>E. coli</i> , anaerobes (depending on site)
Deep infection	Depends on anatomical location
Burns	Gram-positive cocci, <i>Pseudomonas</i> spp., <i>Candida albicans</i>
Immunocompromised patients	Any of the above

empiric regimen and if there has been recent healthcare contact (or the sepsis develops during a hospital admission) potentially-resistant hospital-acquired organisms may be responsible. Antibiotic therapy should be reviewed daily as the illness progresses and the results of investigations become available. The general management of the sepsis syndrome is covered on [page 885](#).

Meningococcal septicaemia

Neisseria meningitidis is found worldwide, in five major serogroups. In sub-Saharan Africa and parts of Asia where group A meningococcus is prevalent it usually causes epidemic disease. Groups Y and W can also cause epidemic infection, while groups B and C (which are the predominant strains in Europe and North America) tend to be sporadic.

Man is the only known reservoir for the organism, which is carried asymptomatically in the nasopharynx of 5–20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream: this only happens in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has taken place and following viral upper respiratory infections.

Clinical features

Invasive meningococcal infection may cause meningitis, septicaemia or both. Meningitic disease (see Chapter 16) usually presents with the classical triad of headache, fever and neck stiffness. Vomiting, diminished consciousness and focal neurological signs occur, although some patients, especially in the early stages, only have mild symptoms. Meningococcal septicaemia causes the typical features of septic shock such as fever, myalgia and hypotension (see Chapter 16) and may be accompanied by a petechial or haemorrhagic rash ([Fig. 4.26](#)). In some cases, the patient can deteriorate rapidly, with shock, disseminated intravascular coagulation and multiorgan failure.

Diagnosis

The presence of meningitis and septicaemia with a typical rash is strongly suggestive of meningococcal disease. Gram-negative diplococci may be seen on Gram stain of CSF or of aspirate from petechiae and meningococci can also be cultured from CSF or blood, or detected by PCR.

Figure 4.26 Meningococcal infection, showing a purpuric rash.

Management

N. meningitidis is sensitive to benzylpenicillin (in most cases), third-generation cephalosporins and chloramphenicol: antibiotic treatment for meningococcal meningitis should be started **immediately** (see [Emergency Box 22.1](#), [p. 1127](#)) and continued parenterally for 7 days. Meningococcal septicaemia should be managed in the same way as any other septicaemic illness. The mortality from meningococcal septicaemia in developed countries is currently approximately 10%, while that from meningococcal meningitis alone is less than 5% (see below). Mild neurological sequelae (especially vestibular nerve damage) are common, but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine has contributed to an overall reduction of invasive meningococcal disease in the UK: just over 1000 cases were reported in England and Wales in 2009, compared with 2784 in 1999 (when the group C meningococcal immunization programme began). A serogroup B vaccine is not currently available but is under development. A combined A/C/W135/Y vaccine is available for control of outbreaks caused by these strains and for travellers to endemic areas.

Close contacts of a case of meningococcal disease should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx and reduce the risk of onward spread. In the case of group C disease, contacts should be offered immunization.

Rheumatic fever

Rheumatic fever is an inflammatory disease that occurs in children and young adults (the first attack usually occurs at between 5 and 15 years of age) as a result of infection with group A streptococci. It affects the heart, skin, joints and central nervous system. It is common in the Middle and Far East, Eastern Europe and South America. It is rare in the UK, Western Europe and North America. This decline in the incidence of rheumatic fever (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely due to improved hygiene and the use of antibiotics.

Pharyngeal infection with group A streptococcus is followed by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell wall M proteins of the infecting *Streptococcus pyogenes* and cardiac myosin and laminin. The condition is not due to direct infection of the heart or to the production of a toxin.

Quagliarello V. Dissemination of *Neisseria meningitidis*. *N Engl J Med* 2011; 364:1573–1575.

Table 4.33 Modified Jones criteria for the diagnosis of rheumatic fever

Evidence of antecedent streptococcal infection
Positive throat culture for group A streptococcus
Good clinical history (e.g. of scarlet fever)
Elevated antistreptolysin O titre (or other serological assay for streptococci)
Major criteria
Carditis
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules
Minor criteria
Fever
Arthralgia (unless arthritis counted as major criterion)
Previous rheumatic fever
Raised ESR/C-reactive protein
Leucocytosis
Prolonged PR interval on ECG (unless carditis counted as major criterion)

ESR, erythrocyte sedimentation rate.

Clinical features

The disease presents suddenly, with fever, joint pains and malaise. Diagnosis relies on the presence of two or more major clinical manifestations or one major manifestation plus two or more minor features, in addition to evidence of current or recent streptococcal infection. These are known as the modified Jones criteria (Table 4.33).

Carditis manifests as:

- New or changed heart murmurs
- Development of cardiac enlargement or cardiac failure
- Appearance of a pericardial effusion and ECG changes of pericarditis, myocarditis, AV block, or other cardiac arrhythmias.

Non-cardiac features include the following:

- Fever
- The arthritis associated with rheumatic fever is classically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles and wrists. Once the acute inflammation disappears, the rheumatic process leaves the joints normal
- Sydenham's chorea (or St Vitus' dance, see p. 1121) is involvement of the central nervous system that develops late after a streptococcal infection. Sufferers are noticeably 'fidgety' and display spasmodic, unintentional choreiform movements. Speech is often affected
- Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases. The erythematous areas found mostly on the trunk and limbs coalesce into crescentic ring-shaped patches. Subcutaneous nodules, which are painless, pea-sized, hard nodules beneath the skin, may also occur.

Investigations

- **Throat swabs** are cultured for the group A streptococcus.
- Antistreptolysin O titre and antiDNase B may be elevated.
- ESR and CRP are usually high.
- **Cardiac investigations**, e.g. ECG, echocardiogram, may show evidence of carditis.

Treatment

Absolute bed rest is usually recommended, although the evidence for this dates from the pre-antibiotic era. It is probably reasonable to start mobilizing the patient when acute symptoms start to improve.

Residual streptococcal infections should be eradicated with oral phenoxymethylpenicillin 500 mg four times daily for 1 week. This therapy should be administered even if nasal or pharyngeal swabs do not culture the streptococci.

The arthritis of rheumatic fever usually responds to NSAIDs, although these have no impact on long-term cardiac sequelae. There is no good evidence that steroids are of benefit, although some experts give high-dose prednisolone if there is severe carditis. Recurrences are most common when persistent cardiac damage is present and are prevented by the continued administration of oral phenoxymethylpenicillin 250 mg twice daily or intramuscular benzathine penicillin G 1.2 million units monthly until the age of 20 years or for 5 years after the latest attack (see p. 87). Erythromycin or clarithromycin is used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated promptly.

Prognosis

More than 50% of those who suffer acute rheumatic fever with carditis will later (after 10–20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves.

Leptospirosis

Leptospirosis is a zoonosis caused by the spirochaete *Leptospira interrogans*. There are over 200 serotypes: the main types affecting humans are *L. i. icterohaemorrhagiae* (rodents); *L. i. canicola* (dogs and pigs); *L. i. hardjo* (cattle) and *L. i. pomona* (pigs and cattle). Leptospirae are excreted in the animal's urine and enter the host through a skin abrasion or through intact mucous membranes. Leptospirosis can also be caught by ingestion of contaminated water. The organism can survive for many days in warm fresh water and for up to 24 h in sea water.

In England and Wales, only about 50 cases of leptospirosis are reported every year (although many mild infections probably go undiagnosed) and it remains largely an occupational disease of farmers, vets and others who work with animals. In some parts of the world (e.g. Hawaii, where the annual incidence is high) it is associated with a variety of recreational activities which bring people into closer contact with rodents. Outbreaks of leptospirosis have also been associated with flooding.

Clinical features

In 1896 Weil, described a severe illness consisting of jaundice, haemorrhage and renal impairment caused by *L. i. icterohaemorrhagiae*, but fortunately 90–95% of infections are subclinical or cause only a mild fever. The incubation period of leptospirosis is usually 7–14 days and the illness typically has two phases. A leptospiraemic phase, which lasts for up to a week, is followed after a couple of days' interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy and various skin rashes are sometimes seen. The second phase is usually mild. Fifty per cent of patients have meningism, about a third of whom have a CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

Skalsky K, Yahav D, Bishara J et al. Treatment of human brucellosis: systematic review and meta-analysis of randomised controlled trials. *BMJ* 2008; 336:701–704.

In severe disease there may not be a clear distinction between phases. Following the initial symptoms, patients progressively develop hepatic and kidney injury, haemolytic anaemia and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care the mortality is around 10%, rising to 15–20% in the elderly.

Diagnosis

The diagnosis is usually a clinical one. *Leptospire*s can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. A minority of patients may also excrete the organism in their urine from the second week onwards. Confirmation is usually serological. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutination test (MAT) showing a four-fold rise. There is typically a leucocytosis and in severe infection, thrombocytopenia and an elevated creatine phosphokinase.

Management

Early antibiotic therapy will limit the progress of the disease, but treatment should still be initiated whatever the stage of the infection. Oral doxycycline may be used in mild cases: intravenous penicillin, ceftriaxone, or ciprofloxacin is given in more severe disease. Intensive supportive care is needed for those patients who develop hepatorenal failure.

Brucellosis

Brucellosis (Malta fever, undulant fever) is a zoonosis and has a worldwide distribution, although it has been virtually eliminated from cattle in the UK where there have been few infections – mainly imported – in recent years. The highest incidence is in the Mediterranean countries, the Middle East and the tropics; there are about 500 000 new cases diagnosed per year worldwide.

The organisms usually gain entry into the human body via the mouth; less frequently they may enter via the respiratory tract, genital tract, or abraded skin. The bacilli travel in the lymphatics and infect lymph nodes. This is followed by haematogenous spread with ultimate localization in the reticulo-endothelial system. Acquisition is usually by the ingestion of raw milk from infected cattle or goats, although occupational exposure is also common. Person-to-person transmission is rare.

Clinical features

The incubation period of acute brucellosis is 1–3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia and night sweats. The fever pattern is classically undulant, although continuous and intermittent patterns are also seen. Lymphadenopathy and hepatosplenomegaly are common; sacroiliitis, arthritis, osteomyelitis, epididymo-orchitis, meningoencephalitis and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting a year or more. This is characterized by easy fatigability, myalgia and occasional bouts of fever and depression. Splenomegaly is usually present. Occasionally infection can lead to localized brucellosis. Bones and joints, spleen, endocardium, lungs, urinary tract and nervous system may be involved. Systemic symptoms occur in less than one-third.

Diagnosis

Blood (or bone marrow) cultures are positive during the acute phase of illness in 50% of patients (higher in *B. melitensis*),

but prolonged culture is needed. In chronic disease serological tests are of greater value. The brucella agglutination test, which demonstrates a fourfold or greater rise in titre (>1 in 160) over a 4-week period, is highly suggestive of brucellosis. An elevated serum IgG level is evidence of current or recent infection; a negative test excludes chronic brucellosis. In localized brucellosis antibody titres are low and diagnosis is usually established by culturing the organisms from the involved site. Species-specific PCR tests are also available.

Management and prevention

Brucellosis should be treated with a combination of doxycycline, rifampicin and an aminoglycoside (usually gentamicin). Prevention and control involve careful attention to hygiene when handling infected animals, vaccination with the eradication of infection in animals and pasteurization of milk. No vaccine is available for use in humans.

Listeriosis

Listeria monocytogenes is an environmental organism which is widely disseminated in soil and decayed matter. It affects both animals and man: the most common route of human infection is in contaminated foodstuffs. The organism can grow at temperatures as low as 4°C and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables and chicken pâtés. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant women, the elderly and the immunocompromised. *L. monocytogenes* has also been recognized as a cause of self-limiting food-borne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnant women, *Listeria* causes a flu-like illness, but infection of the fetus can lead to septic abortion, premature labour and stillbirth. Early treatment of *Listeria* in pregnancy may prevent this, but the overall fetal loss rate is about 50%. In the elderly and the immunocompromised *Listeria* can cause meningoencephalitis. Septicaemia and a variety of other focal infections have also been described.

The diagnosis is established by culture of blood, CSF, or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole is also effective, but the organism is resistant to cephalosporins.

Q fever

Q fever is a zoonosis caused by *Coxiella burnetii*, which is classified as the gamma subdivision of the Proteobacteria based on RNA sequencing. Infection is widespread in domestic, farm and other animals, birds and arthropods: spread is mainly by ticks. Modes of transmission to humans are by dust, aerosol and unpasteurized milk from infected cows. The formation of spores means that *C. burnetii* can survive in extreme environmental conditions for long periods. The infective dose is very small, so that minimal animal contact is required. One reported outbreak occurred among inhabitants of a village through which infected sheep had passed. Infection in the UK is rare and is usually associated with farm and abattoir workers. A large and ongoing outbreak in the Netherlands (with 3500 human cases) has been linked to intensive farming facilities.

Clinical features

Symptoms begin insidiously 2–4 weeks after infection. Fever is accompanied by flu-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously but pneumonia or hepatitis may develop. Occasionally infection

FURTHER READING

Parker NR, Barralet JH, Bell AM. Q fever. *Lancet* 2006; 367:679–683.

can become chronic, with endocarditis, myocarditis, uveitis, osteomyelitis or other focal infections.

C. burnetii is an obligate intracellular organism and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens allow distinction between acute and chronic infection. A PCR assay is available, but the sensitivity is low.

Management

Treatment with doxycycline 200 mg daily for 2 weeks reduces the duration of the acute illness, but it is not known whether this correlates with eradication of the organism. Azithromycin is also used. For chronic Q fever, including endocarditis, doxycycline is often combined with hydroxychloroquine. Even prolonged courses of treatment may not clear the infection. A vaccine is available for those at high risk.

Lyme disease

Lyme disease is caused by a spirochaete, *Borrelia burgdorferi*, which has at least 11 different genomic species. It is a zoonosis of deer and other wild mammals. The disease has increased in both incidence and detection: it is now known to be widespread in the USA, Europe, Russia and the Far East. About 800 autochthonous cases are seen in England and Wales each year. Infection is transmitted from animal to man by ixodid ticks and is most likely to occur in rural wooded areas in spring and early summer. Deer are the main animal reservoir.

Clinical features

There are three stages of Lyme infection:

- Stage 1 disease is a localized infection, presenting about a week after the tick bite with erythema migrans (a macular rash), lymphadenopathy, and associated fever and headache.
- Stage 2 disease occurs several days to weeks after the appearance of erythema migrans. Some patients may develop a more widespread rash, and after several weeks or months around 15% of untreated cases develop neurological complications such as meningitis, encephalitis, cranial or peripheral neuritis, or radiculopathies. About 5% of patients develop cardiac involvement. Myalgia and arthritis may also occur at this stage.
- Stage 3 disease commonly causes a chronic arthritis (usually of the knees), but may also cause chronic encephalomyelitis and other neurological disorders or acrodermatitis chronica atrophicans. The evidence for persistent infection at this stage is lacking.

Diagnosis

The clinical features and epidemiological considerations are usually strongly suggestive. The diagnosis can only rarely be confirmed by isolation of the organisms from blood, skin lesions, or CSF. IgM antibodies are detectable in the first month and IgG antibodies are invariably present late in the disease. Sensitive antibody detection tests are available but false-positive results occur and an initial positive test should always be followed by a confirmatory immunoblot assay. Even a genuine positive IgG result may be a marker of previous exposure rather than of ongoing infection.

Management

Amoxicillin or doxycycline given early in the course of the disease shortens the duration of the illness in approximately 50% of patients. Late disease should be treated with 2–4

weeks of intravenous ceftriaxone. However, treatment is unsatisfactory and preventative measures are recommended. In tick-infested areas, repellents and protective clothing should be worn. Prompt removal of any tick is essential as infection is unlikely to take place unless the tick has been attached for more than 48 h. Ticks should be grasped with forceps near to the point of attachment to the skin and then withdrawn by gentle traction. Antibiotic prophylaxis following a tick bite is not usually justified, even in areas where Lyme disease is common. There is currently no effective vaccine.

Tularaemia

Tularaemia is due to infection by *Francisella tularensis*, a Gram-negative organism. It is primarily a zoonosis, acquired mainly from rodents. Infection can be transmitted by arthropod vectors or by handling infected animals, when the microorganisms enter through minor abrasions or mucous membranes. Occasionally, infection occurs from contaminated water or from eating uncooked meat. The disease is widely distributed in North America, Northern Europe and Asia, but the particularly virulent type A subspecies is only seen in the USA. It is relatively rare, occurring mainly in hunters, trappers and others in close contact with animals.

The incubation period of 2–7 days is followed by a generalized illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation. This ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely this can be followed by bacteraemia, leading to septicaemia, pneumonia or meningitis. These forms of the disease carry a high mortality if untreated.

Diagnosis is by culture of the organism or by a rising titre seen on a bacterial agglutination test.

Tularaemia should be treated with streptomycin or gentamicin, although doxycycline is used in mild disease.

BACTERIAL INFECTIONS SEEN IN DEVELOPING AND TROPICAL COUNTRIES

Skin, soft tissue and eye disease

Leprosy

Leprosy is caused by the acid-fast bacillus *Mycobacterium leprae*. Unlike other mycobacteria, this does not grow in artificial media or even in tissue culture. Apart from the nine-banded armadillo, man is the only natural host of *M. leprae*, although it can be grown in the footpads of mice.

The WHO campaign to control leprosy has been hugely successful, with more than 14 million people having been cured of the disease. The number of people with active leprosy has fallen from 5.4 million in 1985, to about 213 000 at the end of 2008, largely as the result of supervised multi-drug treatment regimens. The majority of the remaining cases are in India and Brazil and despite the successes, many new infections are occurring in these countries.

The precise mode of transmission of leprosy is still uncertain but it is likely that nasal secretions play a role. Infection is related to poverty and overcrowding. Once an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males appear to be more susceptible than females and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host's cell-mediated immune system.

Skin lesion erythema migrans at the site of the tick bite.

FURTHER READING

Stanek G. Lyme borreliosis. *Lancet* 2012; 379:461–473.

Two *polar* types of leprosy are recognized (Fig. 4.27):

- **Tuberculoid leprosy**, a localized disease that occurs in individuals with a high degree of cell-mediated immunity (CMI). The T-cell response to the antigen releases interferon which activates macrophages to destroy the bacilli (Th1 response) but with associated destruction of the tissue.
- **Lepromatous leprosy**, a generalized disease that occurs in individuals with impaired CMI (Fig. 4.27). Here the tissue macrophages fail to be activated and the bacilli multiply intracellularly. Th2 cytokines are produced.

The WHO classification of leprosy depends on the number of skin lesions and the number of bacilli detected on the skin smears: *paucibacillary leprosy* has five or fewer skin lesions with no bacilli; *multibacillary leprosy* has six or more lesions which may have bacilli.

In practice, many patients will fall between these two extremes and some may move along the spectrum as the disease progresses or is treated.

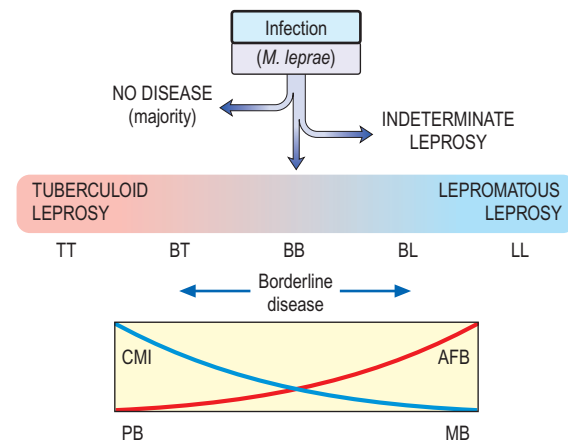

Figure 4.27 Clinical spectrum of leprosy with the combined Ridley–Jopling and WHO classification. BT, borderline tuberculoid; BB, borderline; BL, borderline lepromatous; CMI, cell-mediated immunity; AFB, acid-fast bacilli; PB, paucibacillary; MB, multibacillary.

Clinical features

The incubation period varies from 2 to 6 years, although it may be as short as a few months or as long as 20 years. The onset of leprosy is generally insidious (although acute onset is known to occur). Patients may present with a transient rash, features of an acute febrile illness, evidence of nerve involvement, or with any combination of these.

The spectrum of disease can be divided into five clinical groups (Fig. 4.28).

Diagnosis

The diagnosis of leprosy is essentially clinical with:

- hypopigmented/reddish patches with loss of sensation
- thickening of peripheral nerves
- acid-fast bacilli (AFB) seen on skin-slit smears/biopsy. Small slits are made in pinched skin and the fluid obtained is smeared on a slide and stained for AFB.

Patients should be examined for skin lesions in adequate natural light. Occasionally nerve biopsies are helpful. Detection of *M. leprae* DNA is possible in all forms of leprosy using the polymerase chain reaction and can be used to assess the efficacy of treatment.

Management

Multidrug therapy (MDT) is essential because of developing drug resistance (up to 40% of bacilli in some areas are resistant to dapsone). Much shorter courses of treatment are now being used: the current WHO recommended drug regimens for leprosy are shown in Box 4.12 but longer therapy is required in severe cases. Follow-up, including skin smears, is obligatory. Immunological reactions ('lepra reactions') can occasionally occur after starting treatment, especially in borderline and lepromatous disease (Box 4.13).

Patient education is essential. Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. If ulcers develop, no weight-bearing should be permitted. Cheap canvas shoes with cushioned insoles are protective.

Leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in

the management of trophic ulcers and deformities of the hands, feet and face.

Prevention

The prevention and control of leprosy depends on rapid treatment of infected patients, particularly those with LL and BL, to decrease the bacterial reservoir.

Anthrax

Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production and this property correlates most closely with its virulence. The disease occurs worldwide, but it is most common in Africa and Southern Asia. Transmission is through direct contact with an infected animal; infection is most frequently seen in farmers, butchers and dealers in wool and animal hides. Spores can also be ingested or inhaled. There have been cases in the USA due to the deliberate release of anthrax spores as a bioterrorist weapon (see p. 936).

Clinical features

The incubation period is 1–10 days. Cutaneous anthrax is the most common. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in the majority of patients, but occasionally perivesicular oedema and regional lymphadenopathy may be marked and toxæmia can occur.

Inhalational anthrax (wool sorter's disease) follows inhalation of spores. A febrile illness is accompanied by non-productive cough and retrosternal discomfort; pleural effusions are common. Untreated, the mortality is about 90% and in the bioterrorism cases in the USA it was 45% despite treatment.

Gastrointestinal anthrax is due to consumption of undercooked, contaminated meat. It presents as severe gastroenteritis; haematemesis and bloody diarrhoea can occur. Toxaemia, shock and death may follow.

Diagnosis

The diagnosis is established by demonstrating the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be made using ELISAs detecting antibodies to both the organism and a toxin.

Management

Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate but therapy for 60 days was used in the recent outbreaks in the USA. In more severe infections, high doses of intravenous antibiotics are needed, along with appropriate supportive care. A new monoclonal antibody, raxibacumab, has been shown in animal studies to improve survival in inhalation anthrax. Any suspected case should be reported to the relevant authority.

Control

Any infected animal that dies should be burned and the area in which it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination, but needs to be repeated annually. A human vaccine is available for those at high risk and prophylactic antibiotics may be indicated following exposure. Some countries are establishing public health policies to deal with the deliberate release of anthrax spores.

Mycobacterial ulcer (buruli ulcer)

Buruli ulcer, caused by *Mycobacterium ulcerans*, is seen in humid rural areas of the tropics, especially in Africa. The mode of transmission is thought to be via infected water bugs living in pools and muddy fields. A small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone (a toxin produced by the mycobacterium). Smears taken from necrotic tissue generally reveal numerous acid-fast bacilli. Until recently, the only effective treatment was wide surgical excision with skin grafts, but this is often unavailable in areas where the disease is prevalent. Combination therapy with rifampicin and clarithromycin has shown significant benefit in some forms of the disease and early evidence suggests that the oral combination of rifampicin and clarithromycin may also work.

Endemic treponematoses (bejel, yaws and pinta)

These diseases are found in various parts of the tropics and subtropics, mainly in impoverished rural areas. The WHO treated over 50 million cases in the 1950s and 1960s, reducing the prevalence, but subsequently there has been a resurgence of infection. The latest estimate of global prevalence is 2.5 million cases, mainly in South America and Africa (India has recently declared the eradication of yaws). Improvements in sanitation and an increase in living standards will be required to eradicate the diseases completely as organisms are transmitted by bodily contact, usually in children, the organism entering through damaged skin.

Clinical features

Yaws

Yaws (caused by *Treponema pertenue*) is the most widespread and common of the endemic treponemal diseases. After an incubation period of weeks or months a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple papular lesions containing treponemes; these skin lesions usually involve the palms and soles. There may also be bone involvement, particularly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatous lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, the interphalangeal joints and the long bones. Plantar hyperkeratosis is characteristic. Like syphilis, there may be a latent period between the early and late phases of the disease, but visceral, neurological and cardiovascular problems do not occur.

Bejel (endemic syphilis)

Bejel is seen in Africa and the Middle East. The causative organism (*Treponema endemicum*) enters through abrasions in the skin directly or by mouth-to-mouth or skin-to-skin contact indirectly. It differs from venereal syphilis in that a primary lesion is not commonly seen. The late stages resemble syphilis, but cardiological and neurological manifestations are rare.

Pinta

Pinta, caused by *Treponema carateum*, is restricted mainly to Central and South America. It is milder than the other treponematoses and is confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates and is generally associated with regional lymphadenopathy. In the later stages similar lesions can continue to occur for up to 1 year, associated with generalized lymphadenopathy. Eventually the lesions heal leaving hyperpigmented or depigmented patches.

Diagnosis and management

In endemic areas the diagnosis is usually clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive and do not differentiate between the conditions.

The treatment is with long-acting penicillin (e.g. intramuscular benzathine penicillin, 1.2 million units) given as a single dose. Single dose oral azithromycin gives as good results. Doxycycline is used when penicillin is ineffective or contraindicated.

Trachoma

Trachoma, caused by the intracellular bacterium *Chlamydia trachomatis*, is the most common cause of blindness in the world. It is estimated that there are 150 million current infections and 6 million people who have been blinded by trachoma. It is a disease of poverty which is found mainly in the tropics and the Middle East: it is entirely preventable. Trachoma commonly occurs in children and is spread by direct transmission or by flies. Isolated infection is probably self-limiting and it is repeated infection which leads to chronic eye disease.

Clinical features

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Scarring of the upper eyelid causes entropion, leaving the cornea exposed to further damage with the eyelashes rubbing against it (trichiasis). The corneal scarring that eventually occurs leads to blindness.

Trachoma may also occur as an acute ophthalmic infection in the neonate.

Diagnosis and management

The diagnosis is generally made clinically. However, this is an unreliable indicator of active infection. A newly developed near-patient immunodiagnostic dipstick test may help to better target antibiotic therapy.

Systemic therapy with a single dose of azithromycin 20 mg/kg is the treatment of choice; although tetracycline ointment applied locally each day for 6–8 weeks is effective, compliance is poor. In endemic areas repeated courses of therapy are necessary. Once infection has been controlled, surgery may be required for eyelid reconstruction and for treatment of corneal opacities.

Prevention

Community health education, improvements in water supply and sanitation (pit latrines) and earlier case reporting could have a substantial impact on disease prevalence. This is reflected in the 'SAFE' approach to trachoma: surgery, antibiotics, facial cleanliness, environmental improvement. A WHO target is global eradication by 2020.

Gastrointestinal infections

Cholera

Cholera is caused by the curved, flagellated Gram-negative bacillus, *Vibrio cholerae*. The organism is killed by temperatures of 100°C in a few seconds but can survive in ice for up to 6 weeks. One major pathogenic serogroup possesses a somatic antigen (O1) with two biotypes: classical and El Tor. The El Tor biotype replaced the classical biotype as the major cause of the seventh pandemic which began in the 1960s. Infection with the El Tor biotype generally causes milder symptoms, but can still cause severe and life-threatening disease.

The fertile, humid Gangetic plains of West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. The seventh pandemic currently affects large areas of Asia and sub-Saharan Africa. A new serogroup (O139 Bengal) is responsible for many cases in Bangladesh, India and South-east Asia.

Transmission is by the faeco-oral route. Contaminated water plays a major role in the dissemination of cholera, although contaminated foodstuffs and contact carriers may

contribute in epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. Here they proliferate, elaborating an exotoxin which produces massive secretion of isotonic fluid into the intestinal lumen (see p. 292). Cholera toxin also releases serotonin (5-HT) from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin's secretory activity. *V. cholerae* also produces other toxins (zona occludens toxin, ZOT and accessory cholera toxin, ACT) which contribute to its pathogenic effect.

Clinical features

The incubation period varies from a few hours to 6 days. The majority of patients with cholera have a mild illness that cannot be distinguished clinically from diarrhoea due to other infective causes. In severe cases, there is abrupt onset of profuse painless diarrhoea, followed by vomiting. As the illness progresses the typical 'rice water' stool, flecked with mucus, may be seen. There is massive fluid loss and if this is not replaced the features of hypovolaemic shock (cold clammy skin, tachycardia, hypotension and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks and a diminished urine output) appear. The patient, though apathetic, is usually lucid. Muscle cramps may be severe. Children may present with convulsions owing to hypoglycaemia.

With adequate treatment the prognosis is good, with a gradual return to normal clinical and biochemical parameters in 1–3 days.

Diagnosis

This is largely clinical. Examination of freshly passed stools may demonstrate rapidly motile organisms (although this is not diagnostic, as *Campylobacter jejuni* may give a similar appearance). A rapid dipstick test is now also available. Stool and rectal swabs should be taken for culture to confirm the diagnosis and to establish antibiotic sensitivity. Cholera should always be reported to the appropriate public health authority.

Management

The mainstay of treatment is rehydration and with appropriate and effective rehydration therapy mortality has decreased to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is occasionally required (Fig. 4.29).

Oral rehydration solutions (ORS) are based on the observation that glucose (and other carbohydrates) enhance sodium and water absorption in the small intestine, even in the presence of secretory loss due to toxins. Additions such as amylase-resistant starch to glucose-based ORS have been shown to increase the absorption of fluid. Cereal-based electrolyte solutions have been found to be as effective as sugar/salt ORS and actually reduce stool volume as well as rehydrating. The WHO recommends the use of reduced osmolality ORS for all types of diarrhoea, although concerns remain about the risk of hyponatraemia. Suitable solutions for rehydration are listed in Box 4.10 (see p. 124).

Immunization is now recommended by the WHO in potential or actual outbreak situations. Live attenuated and killed vaccine (both oral) are available: neither protect against the O139 strain. The best preventative measures, however, are good hygiene and improved sanitation.

Enteric fever

Over 17 million new cases of enteric fever occur worldwide, mainly in India and Africa, causing 600 000 deaths per year.

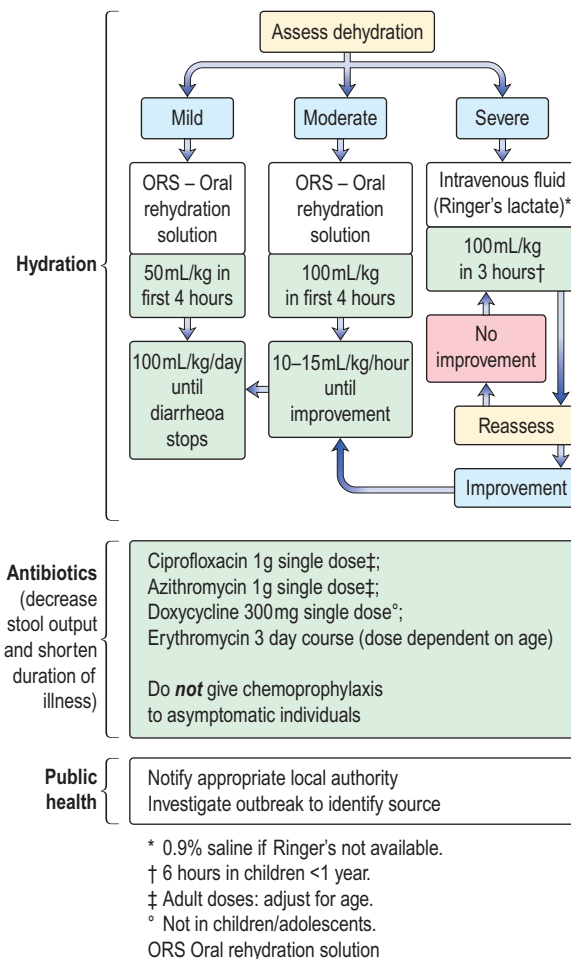

Figure 4.29 The management of cholera.

Enteric fever is an acute systemic illness characterized by fever, headache and abdominal discomfort. *Typhoid*, the typical form of enteric fever, is caused by *Salmonella typhi*. A similar but generally less severe illness known as paratyphoid is due to infection with *S. paratyphi* A, B or C. Man is the only natural host for *S. typhi*, which is transmitted in contaminated food or water. The incubation period is 10–14 days.

Clinical features

After ingestion, the bacteria invade the small bowel wall via Peyer's patches, from where they spread to the regional lymph nodes and then to the blood. The onset of illness is insidious and nonspecific, with intermittent fever, headache and abdominal pain. Physical findings in the early stages include abdominal tenderness, hepatosplenomegaly, lymphadenopathy and a scanty maculopapular rash ('rose spots'). Without treatment (and occasionally even after treatment) serious complications can arise, usually in the third week of illness. These include meningitis, lobar pneumonia, osteomyelitis, intestinal perforation and intestinal haemorrhage. The fourth week of the illness is characterized by gradual improvement, but in developing countries up to 30% of those infected will die and 10% of untreated survivors will relapse. This compares with a mortality rate of 1–2% in the USA.

After clinical recovery 5–10% of patients will continue to excrete *S. typhi* for several months: these are termed convalescent carriers. Between 1% and 4% will continue to carry the organism for more than a year: this is chronic carriage.

The usual site of carriage is the gall bladder and chronic carriage is associated with the presence of gallstones. However, in parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of *S. typhi* in the urinary bladder is also common.

Diagnosis

The definitive diagnosis of enteric fever requires the culture of *S. typhi* or *S. paratyphi* from the patient. Blood culture is positive in most cases in the first 2 weeks. Culture of intestinal secretions, faeces and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is more sensitive than blood culture, but is rarely required except in patients who have already received antibiotics. Leucopenia is common but non-specific. Serological tests such as the Widal antigen test are of little practical value, are easily misinterpreted and should not be used.

Management

Increasing antibiotic resistance is seen in isolates of *S. typhi*, especially in the Indian subcontinent. Chloramphenicol, cotrimoxazole and amoxicillin may all still be effective in some cases, but quinolones (e.g. ciprofloxacin 500 mg twice daily) are now the treatment of choice, although increased resistance to these agents is being seen: in such cases azithromycin may be effective. The patient's temperature may remain elevated for several days after starting antibiotics and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier state, but in the presence of gall bladder disease it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

Prevention

This is mainly through improved sanitation and clean water. Travellers should avoid drinking untreated water, ice in drinks

and eating ice creams. Vaccination with either injectable inactivated or oral live attenuated vaccines give partial protection.

Systemic infections

Tuberculosis

Tuberculosis is caused by *Mycobacterium tuberculosis* and occasionally *M. bovis* or *M. africanum*. These are slow-growing bacteria and, unlike other mycobacteria, are facultative intracellular organisms. The prevalence of tuberculosis increases with poor social conditions, inadequate nutrition and overcrowding. In developing countries it is most commonly acquired in childhood.

The impact of tuberculosis in the developing world has been magnified in the past 20 years by the emergence of the HIV pandemic (see p. 171) (Fig. 4.30).

Widespread misuse of antibiotics, combined with the breakdown of healthcare systems in parts of Africa, Russia and East Europe, has led to the emergence of drug-resistant tuberculosis. Multidrug-resistant tuberculosis (MDRTB) is caused by bacteria that are resistant to both rifampicin and isoniazid, two drugs which form the mainstay of treatment. It is now widespread in many parts of the world, including Asia, Eastern Europe and Africa. Extensively drug-resistant TB (XDRTB) is additionally resistant to quinolones and injectable second-line agents. MDRTB, and especially XDRTB, are very difficult to treat and carry significant mortality even with the best medical care (see p. 843).

In most people, the initial primary tuberculosis is asymptomatic or causes only a mild illness. The focus of the disease heals.

Occasionally the primary infection progresses locally to a more widespread lesion. Haematogenous spread at this stage may give rise to miliary tuberculosis.

Figure 4.30 Tuberculosis: geographical distribution. (From Frieden TR, Sterling TR, Munsiff SS et al. *Tuberculosis*. Lancet 2003; 362:888, with permission from Elsevier.)

Tuberculosis in the adult is usually the result of reactivation of old disease (post-primary tuberculosis), but primary infection, or more rarely reinfection, also occurs.

Pulmonary tuberculosis is the most common form; this is described on page 839, along with the chemotherapeutic regimens. Tuberculosis also affects other parts of the body.

- The gastrointestinal tract, mainly the ileocaecal area, but occasionally the peritoneum, producing ascites (see p. 269)
- The genitourinary system. The kidneys are most commonly involved, but tuberculosis can also cause painless, craggy swellings in the epididymis and salpingitis, tubal abscesses and infertility in females
- The central nervous system, causing tuberculous meningitis and tuberculomas (see p. 1121)
- The skeletal system, causing septic arthritis and osteomyelitis
- The skin, giving rise to lupus vulgaris
- The eyes, where it can cause choroiditis or iridocyclitis
- The pericardium, producing constrictive pericarditis (see p. 776)
- The adrenal glands, causing destruction and producing Addison's disease
- Lymph nodes. This is a common mode of presentation, especially in young adults and children. Any group of lymph nodes may be involved, but hilar and paratracheal lymph nodes are the most common. Initially the nodes are firm and discrete but later they become matted and can suppurate with sinus formation. Scrofula is the term used to describe massive cervical lymph node enlargement with discharging sinuses. Mycobacterial lymph node disease may also be caused by non-tuberculous mycobacteria.

Non-tuberculous mycobacterial infections

The majority of mycobacterial species are environmental organisms and are rarely pathogenic. Some have been found to cause disease in man, particularly in immunocompromised patients or those with pre-existing chronic lung disease (Table 4.34).

Table 4.34 Non-tuberculous mycobacteria causing disease in man		
Clinical	Common cause	Rare cause
Chronic lung disease	<i>Mycobacterium avium-intracellulare</i> <i>M. kansasii</i>	<i>M. malmoeense</i> <i>M. xenopi</i>
Local lymphadenitis	<i>M. avium-intracellulare</i> <i>M. scrofulaceum</i>	<i>M. malmoeense</i> <i>M. fortuitum</i>
Skin and soft tissue infection		
Fish tank granuloma	<i>M. marinum</i>	
Abscesses, ulcers, sinuses	<i>M. fortuitum</i> <i>M. chelonae</i>	<i>M. haemophilum</i>
Bone and joint infection	<i>M. kansasii</i> <i>M. avium-intracellulare</i>	<i>M. scrofulaceum</i>
Disseminated infection (in HIV)	<i>M. avium-intracellulare</i>	

Plague

Plague is caused by *Yersinia pestis*, a Gram-negative bacillus. Sporadic cases of plague (as well as occasional epidemics) occur worldwide: about 2000 cases per year are reported to the WHO, with a 10% mortality. The majority of cases are seen in sub-Saharan Africa, although the disease is occasionally seen in developed countries in people undertaking outdoor pursuits. The main reservoirs are woodland rodents, which transmit infection to domestic rats (*Rattus rattus*). The usual vector is the rat flea, *Xenopsylla cheopis*. These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds, or through inhalation of droplets.

Clinical features

Four clinical forms are recognized: bubonic, pneumonic, septicæmic and cutaneous.

Bubonic plague

This is the most common form and occurs in about 90% of infected individuals. The incubation period is 2–7 days. The onset of illness is acute, with high fever, chills, headache, myalgia, nausea, vomiting and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically these are matted and tender and suppurate in 1–2 weeks.

Pneumonic plague

This is characterized by the abrupt onset of features of a fulminant pneumonia with bloody sputum, marked respiratory distress, cyanosis and death in almost all affected patients.

Septicæmic plague

This presents as an acute fulminant infection with evidence of shock and disseminated intravascular coagulation (DIC). If left untreated, death usually occurs in 2–5 days. Lymphadenopathy is unusual.

Cutaneous plague

This presents either as a pustule, eschar or papule or an extensive purpura, which can become necrotic and gangrenous.

Diagnosis

This is based on clinical, epidemiological and laboratory findings. Microscopy (on blood or lymph node aspirate) or a rapid antigen detection test can provide a presumptive diagnosis in an appropriate clinical setting. Blood or lymph node culture, or paired serological tests, are required for confirmation.

Management

Treatment is urgent and should be instituted before the results of culture studies are available. The treatment of choice is now gentamicin 1 mg/kg i.v. three times daily for 10 days. Oral doxycycline 500 mg four times daily and chloramphenicol are also effective.

Prevention

Prevention of plague is largely dependent on the control of the flea population. Outhouses, or huts, should be sprayed with insecticides that are effective against the local flea. During epidemics rodents should not be killed until the fleas are under control, as the fleas will leave dead rodents to bite humans. Tetracycline 500 mg four times daily for 7 days is

Table 4.35 Infections caused by rickettsiae

Disease	Organism	Reservoir	Vector
Typhus fever group			
Epidemic typhus	<i>Rickettsia prowazekii</i>	Man	Human body louse

Rickettsial pox	<i>R. akari</i>	Rodents	Mite
Flea-borne spotted fever	<i>R. felis</i>	Various mammals	Flea

an effective chemoprophylactic agent. A partially effective formalin-killed vaccine is available for use by travellers to plague-endemic areas.

Relapsing fevers

These conditions are so named because, after apparent recovery from the initial infection, one or more recurrences may occur after a week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

Clinical features

Louse-borne relapsing fever (caused by *B. recurrentis*) is spread by body lice and only humans are affected. Classically it is an epidemic disease of armies and refugees, although it is also endemic in the highlands of Ethiopia, Yemen and Bolivia. Lice are spread from person to person when humans live in close contact in impoverished conditions. Infected lice are crushed by scratching, allowing the spirochaete to penetrate through the skin. Symptoms begin 3–10 days after infection and consist of a high fever of abrupt onset with rigors, generalized myalgia and headache. A petechial or ecchymotic rash may be seen. The general condition then deteriorates, with delirium, hepatosplenomegaly, jaundice, haemorrhagic problems and circulatory collapse. Although complete recovery may occur at this time, the majority experience one or more relapses of diminishing intensity over the weeks following the initial illness. The severity of the illness varies enormously and some cases have only mild symptoms. However, in some epidemics mortality has exceeded 50%.

Tick-borne relapsing fever is caused by *B. duttoni* and other *Borrelia* species, spread by soft (argasid) ticks. Rodents are also infected and humans are incidental hosts, acquiring the spirochaete from the saliva of the infected tick. This disease is mainly found in countries where traditional mud huts are the form of shelter and is a common cause of febrile illness in parts of Africa. The illness is generally similar to the louse-borne disease, although neurological involvement is more common.

Diagnosis and management

Spirochaetes can be demonstrated microscopically in the blood during febrile episodes: organisms are more numerous in louse-borne relapsing fever. Treatment is usually with tetracycline or doxycycline (see p. 167). A severe Jarisch–Herxheimer reaction (see p. 167) occurs in many patients, often requiring intensive nursing care and intravenous fluids.

Prevention

Control of infection relies on elimination of the vector. Ticks live for years and remain infected, passing the infection to their progeny. These reservoirs of infection should be

controlled by spraying houses with insecticides and by reducing the number of rodents. Patients infested with lice should be deloused by washing with a suitable insecticide. All clothes must be thoroughly disinfected.

Typhus

Typhus is the collective name given to a group of diseases caused by *Rickettsia* species (Table 4.35). *Rickettsiae* (and the closely related *Orientiae*) are small intracellular bacteria that are spread to humans by arthropod vectors, including body lice, fleas, hard ticks and larval mites. *Rickettsiae* inhabit the alimentary tract of these arthropods and the disease is spread to the human host by inoculation of their faeces through broken human skin, generally produced by scratching. *Rickettsiae* multiply intracellularly and can enter most mammalian cells, although the main lesion produced is a vasculitis due to invasion of endothelial cells of small blood vessels. Multisystem involvement is usual.

Clinical features

Typhus fever group

Epidemic typhus. The vector of epidemic typhus is the human body louse and like louse-borne relapsing fever, epidemics are associated with war and refugees. Outbreaks have occurred in Africa, Central and South America and Asia.

The incubation period of 1–3 weeks is followed by an abrupt febrile illness associated with profound malaise and generalized myalgia. Headache is severe and there may be conjunctivitis with orbital pain. A measles-like eruption appears around the fifth day. At the end of the first week, signs of meningoencephalitis appear and CNS involvement may progress to coma. At the height of the illness, splenomegaly, pneumonia, myocarditis and gangrene at the peripheries may be evident. Oliguric renal failure occurs in fulminating disease, which is usually fatal. Recovery begins in the third week but is generally slow. The disease may recur many years after the initial attack owing to rickettsiae that lie dormant in lymph nodes. The recrudescence is known as Brill–Zinsser disease. The factors that precipitate recurrence are not clearly defined, although other infections may play a role.

Endemic (murine) typhus. This is an infection of rodents that is inadvertently spread to humans by rat fleas. The disease closely resembles epidemic typhus but is much milder and rarely fatal.

Scrub typhus. Found throughout Asia and the Western Pacific, this disease is spread by larval trombiculid mites (chiggers). An eschar (a black, crusted, necrotic papule) can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminant and potentially fatal disease. The more severe cases resemble

An eschar developing at the site of the bite.

The petechial rash of rickettsial spotted fever.

epidemic typhus. Unlike other types of typhus the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

Spotted fever group

A variety of *Rickettsia* species, collectively known as the spotted fever group rickettsiae, cause the illnesses known as spotted fevers. In most cases the vector is a hard tick. Although the causative organism and the name of the illness vary from place to place the clinical course is common to all. After an incubation period of 4–10 days, an eschar may develop at the site of the bite in association with regional lymphadenopathy. There is abrupt onset of fever, myalgia and headache, accompanied by a maculopapular rash which may become petechial. Neurological, haematological and cardiovascular complications occur as in epidemic typhus, although these are uncommon.

Diagnosis

The diagnosis is generally made on the basis of the history and clinical course of the illness. It can be confirmed serologically or by PCR.

Treatment and prevention

Doxycycline or tetracycline given for 5–7 days is the treatment of choice. Ciprofloxacin is also effective. Doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline has occurred. Seriously ill patients need intensive care. Control of typhus is achieved by eradication of the arthropod vectors. Lice and fleas can be eradicated from clothing by insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding and in high-risk areas the body should be inspected twice a day as the bites are painless and any ticks should be removed (see p. 130).

Bartonellosis

Bartonella spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms; like rickettsial disease, infection is usually spread from animals via an arthropod vector (Table 4.36).

Carrion's disease (*Bartonella bacilliformis*)

This disease is restricted mainly to the habitat of its main vector, the sandfly, in the river valleys of the Andes

mountains at an altitude of 500–3000 m. Two clinical presentations are seen, which may occur alone or consecutively. *Oroya fever* is an acute febrile illness causing myalgia, arthralgia, severe headache and confusion, followed by a haemolytic anaemia. *Verruga peruana* consists of eruptions of reddish-purple haemangiomatous nodules, resembling bacillary angiomatosis. It may follow 4–6 weeks after Oroya fever, or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrion's disease is frequently complicated by superinfection, especially with *Salmonella* spp.

The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Treatment with chloramphenicol or tetracycline is very effective in acute disease, but less so in verruga peruana.

Cat-scratch disease and bacillary angiomatosis (*Bartonella henselae*)

These are described on page 116.

Trench fever

Trench fever is caused by *Bartonella quintana* and transmitted by human body lice. It is mainly seen in refugees and the homeless. It is characterized by cyclical fever (typically every 5 days), chills and headaches, accompanied by myalgia and pretibial pain. The disease is usually self-limiting but it can be treated with erythromycin or doxycycline if symptoms are severe.

Ehrlichiosis

Ehrlichiosis and anaplasmosis are infections caused by tick-borne rickettsia-like bacteria. At least three species have been implicated: *Ehrlichia chaffeensis*, which causes human monocytic ehrlichiosis (HME), and *E. ewingi* and *Anaplasma phagocytophilum* (formerly known as *E. phagocytophilum*), which cause human granulocytic ehrlichiosis (HGE, also known as human granulocytic anaplasmosis). All cause a rather nonspecific febrile illness with fever, myalgia and headache. Treatment is with doxycycline. The vectors are hard ticks and the main reservoir hosts are deer. As with most tick-borne zoonoses, the avoidance of tick bites and the prompt removal of feeding ticks are the best forms of prevention.

Melioidosis

The term melioidosis refers to infections caused by the Gram-negative bacteria *Burkholderia pseudomallei*. This environmental organism, which is found in soil and surface

Table 4.36 Human infections caused by *Bartonella* spp. and *Ehrlichia* spp.

Disease	Organism	Reservoir	Vector

Human granulocytic ehrlichiosis (HGE) ^a	<i>Ehrlichia ewingi</i> <i>Anaplasma phagocytophilum</i> ^b	Small mammals and deer	Hard ticks

^aAlso known as human granulocytic anaplasmosis.

^bFormerly known as *Ehrlichia phagocytophila*.

water, is distributed widely in the tropics and subtropics. The majority of clinical cases of melioidosis occur in South-east Asia. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have predisposing underlying disease: it is particularly common in diabetics.

B. pseudomallei causes a wide spectrum of disease and the majority of infections are probably subclinical. Illness may be acute or chronic, localized or disseminated, but one form of the disease may progress to another and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses: this is frequently fatal. Serological tests are available, but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. *B. pseudomallei* has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, which is given intravenously for 2–4 weeks; this should be followed by several months of co-amoxiclav to prevent relapses.

Actinomycosis

Actinomyces spp. are branching, Gram-positive higher bacteria which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. *Actinomyces* have a worldwide distribution but are a rare cause of disease in the West.

Clinical features

- **Cervicofacial actinomycosis**, the most common form, usually occurs following dental infection or extraction. It is often indolent and slowly progressive, associated with little pain and results in induration and localized swelling of the lower part of the mandible. Sinuses and tracts develop with discharge of 'sulphur' granules.
- **Thoracic actinomycosis** follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or tuberculosis. Symptoms such as fever, malaise, chest pain and haemoptysis are present. Empyema occurs in 25% of patients and local extension produces chest-wall sinuses with discharge of 'sulphur' granules.
- **Abdominal actinomycosis** most frequently affects the caecum. Characteristically, a hard indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, tuberculosis, Crohn's disease and amoeboma. The incidence of pelvic

actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices.

Occasionally, actinomycosis becomes disseminated to involve any site.

Diagnosis and management

Diagnosis is by microscopy and culture of the organism. Treatment often involves surgery as well as antibiotics: penicillin is the drug of choice. Intravenous penicillin 2.4 g 4-hourly is given for 4–6 weeks, followed by oral amoxicillin for at least 3–4 months after clinical resolution. Tetracyclines are also effective.

Nocardia infections

Nocardia spp. are Gram-positive branching bacteria, which are found in soil and decomposing organic matter. *N. asteroides* and less often *N. brasiliensis* are the main human pathogens.

Clinical features

Mycetoma is the most common illness. This is a result of local invasion by *Nocardia* spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear which eventually rupture and discharge characteristic 'grains', which are colonies of organisms. Systemic symptoms and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria and also by species of eumycete fungi such as *Madurella mycetomi* (see p. 142).

Pulmonary disease, which follows inhalation of the organism, presents with cough, fever and haemoptysis: it is usually seen in the immunocompromised. Pleural involvement and empyema occur. In severely immunosuppressed patients, initial pulmonary infection may be followed by disseminated disease.

Diagnosis and management

The diagnosis is often difficult to establish, as *Nocardia* is not easily detected in sputum cultures or on histological section. Severe pulmonary or disseminated infection may require parenteral treatment. Co-trimoxazole, linezolid, ceftriaxone and amikacin have all been used successfully, but *in vitro* sensitivities are variable and there is no consensus on the best treatment.

FUNGAL INFECTIONS

Morphologically, fungi can be grouped into three major categories:

- Yeasts and yeast-like fungi, which reproduce by budding
- Moulds, which grow by branching and longitudinal extension of hyphae
- Dimorphic fungi, which behave as yeasts in the host but as moulds *in vitro* (e.g. *Histoplasma capsulatum* and *Sporothrix schenckii*).

Despite the fact that fungi are ubiquitous, systemic fungal infections are relatively rare (in contrast to superficial fungal infections of the skin, nails and orogenital mucosae (see p. 1200)). Systemic mycoses are usually seen in immunocompromised patients and in critical care settings and are becoming more prevalent as this population of patients increases.

Fungal infections are transmitted by inhalation of spores, by contact with the skin, or by direct inoculation. This last can occur through penetrating injuries, injecting drug use, or iatrogenic procedures. Fungi may also produce allergic pulmonary disease. Some fungi such as *Candida albicans* are human commensals. Diseases are usually divided into systemic, subcutaneous or superficial (Table 4.37).

Systemic fungal infections

Candidiasis

Candidiasis is the most common fungal infection in humans and is predominantly caused by *Candida albicans* although other species of *Candida* are increasingly recognized. *Candida* are small asexual fungi. Most species that are

pathogenic to humans are normal oropharyngeal and gastrointestinal commensals. Candidiasis is found worldwide.

Clinical features

Any organ in the body can be invaded by candida, but vaginal infection and oral thrush are the most common forms. This latter is seen in the very young, in the elderly, following antibiotic therapy and in those who are immunosuppressed. Candidal oesophagitis presents with painful dysphagia. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia. Balanitis and vaginal infection are also common (see p. 170).

Dissemination of candidiasis may lead to haematogenous spread, with meningitis, pulmonary involvement, endocarditis or osteomyelitis.

Superficial

Dermatophytosis
Superficial candidiasis
Malassezia infections

Diagnosis and treatment

The fungi can be demonstrated in scrapings from infected lesions, tissue secretions or in invasive disease, from blood cultures.

Treatment varies depending on the site and severity of infection. Oral lesions respond to local nystatin or amphotericin B, or systemic fluconazole. For systemic infections, parenteral therapy with amphotericin B, fluconazole, voriconazole or caspofungin is necessary.

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum*, a non-encapsulated, dimorphic fungus. Spores can survive in moist soil for several years, particularly when it is enriched by bird and bat droppings. Histoplasmosis occurs worldwide but is only commonly seen in Ohio and the Mississippi river valleys where over 80% of the population have been subclinically exposed. Transmission is mainly by inhalation of the spores, particularly when clearing out attics, barns and bird roosts or exploring caves.

Clinical features

Figure 4.31 summarizes the pathogenesis, main clinical forms and sequelae of *Histoplasma* infection.

Primary pulmonary histoplasmosis is usually asymptomatic. The only evidence of infection is conversion of a histoplasmin skin test from negative to positive and radiological features similar to those seen with the Ghon primary complex of tuberculosis. Calcification in the lungs, spleen and liver occurs in patients from areas of high endemicity. When symptomatic, primary pulmonary histoplasmosis generally presents as a mild influenza-like illness, with fever, chills, myalgia and cough. The systemic symptoms are pronounced in severe disease.

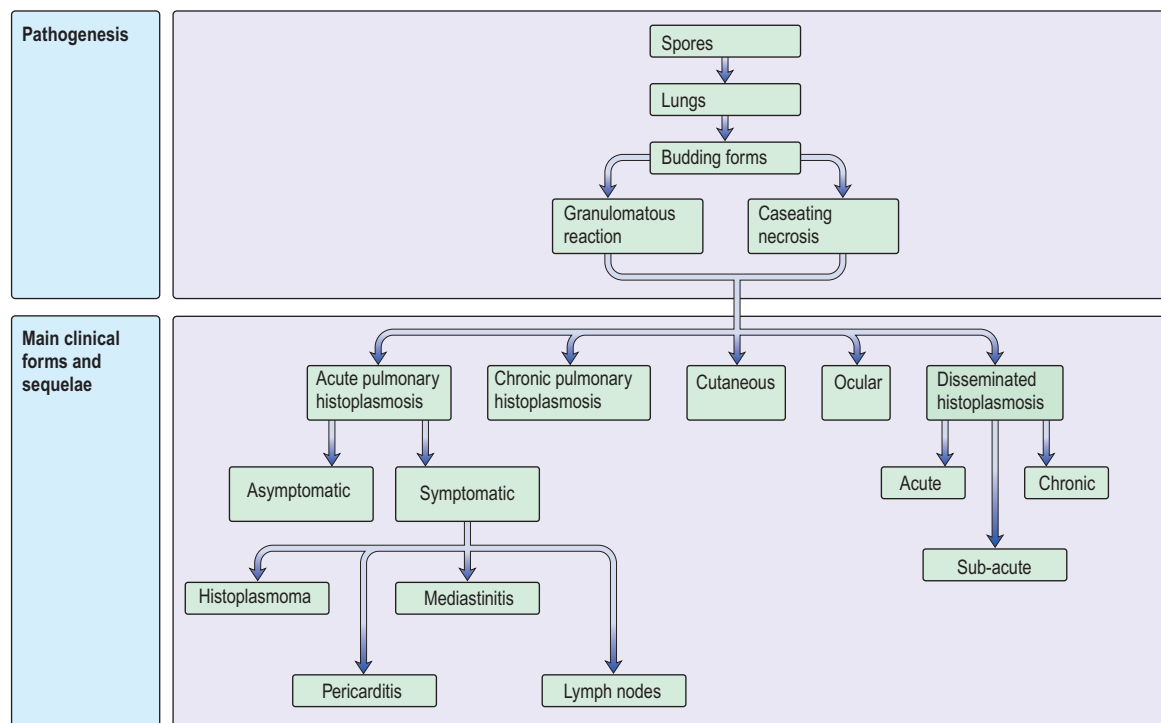

Figure 4.31 Histoplasma infection. Summary of pathogenesis, main clinical forms and sequelae.

Complications such as atelectasis, secondary bacterial pneumonia, pleural effusions, erythema nodosum and erythema multiforme also occur.

Chronic pulmonary histoplasmosis is clinically indistinguishable from pulmonary tuberculosis (see p. 839). It is usually seen in American white males over the age of 50 years. The presentation of disseminated histoplasmosis resembles disseminated tuberculosis clinically. Fever, lymphadenopathy, hepatosplenomegaly, weight loss, leucopenia and thrombocytopenia are common. Rarely, features of meningitis, hepatitis, hypoadrenalism, endocarditis and peritonitis may dominate the clinical picture.

Diagnosis

Definitive diagnosis is possible by culturing the fungi (e.g. from sputum) or by demonstrating them on histological sections. *H. capsulatum* glycoprotein can be detected in the urine and serum in those with acute pulmonary and disseminated infection. Antibodies usually develop within 3 weeks of the onset of illness and are best detected by complement-fixation or immunodiffusion (sensitivity of 95% and 90%, respectively).

Management

Only symptomatic acute pulmonary histoplasmosis, chronic histoplasmosis and acute disseminated histoplasmosis require therapy. Itraconazole is effective in mild-moderate disease. Severe infection is treated with intravenous amphotericin B for 1–2 weeks followed by itraconazole for a total of 12 weeks or with voriconazole. Methylprednisolone is recommended in addition for those who develop respiratory complications. Patients with AIDS usually require treatment with parenteral amphotericin B followed by maintenance therapy with itraconazole 200 mg twice daily where HAART is unavailable. Surgical excision of histoplasmoses (pulmonary granuloma due to *H. capsulatum*) or chronic cavitary lung lesions and release of adhesions following mediastinitis are often required.

African histoplasmosis

This is caused by *Histoplasma duboisii*, the spores of which are larger than those of *H. capsulatum*. Skin lesions (e.g. abscesses, nodules, lymph node involvement and lytic bone lesions) are prominent. Pulmonary lesions do not occur. Treatment is similar to that for *H. capsulatum* infection.

Aspergillosis

Aspergillosis is caused by one of several species of dimorphic fungi of the genus *Aspergillus*. Of these, *A. fumigatus* is the most common, although *A. flavus* and *A. niger* are also recognized. These fungi are ubiquitous in the environment and are commonly found on decaying leaves and trees. Humans are infected by inhalation of the spores. Disease manifestation depends on the dose of the spores inhaled as well as the immune response of the host. Three major forms of the disease are recognized: broncho-pulmonary allergic aspergillosis, aspergilloma and invasive aspergillosis (see p. 829).

The diagnosis and treatment are described in more detail in Chapter 15.

Cryptococcosis

Cryptococcosis is caused by the yeast-like fungus *Cryptococcus neoformans*. It has a worldwide distribution and appears to be spread by birds, especially pigeons, in their

droppings. The spores gain entry into the body through the respiratory tract, where they elicit a granulomatous reaction. Pulmonary symptoms are, however, uncommon; meningitis which usually occurs in those with HIV infection or lymphoma is the usual mode of presentation and often develops subacutely. Less commonly, lung cavitation, hilar lymphadenopathy, pleural effusions and occasionally pulmonary fibrosis occur. Skin and bone involvement is rare.

Diagnosis and treatment

This is established by demonstrating the organisms in appropriately stained tissue sections. A positive latex cryptococcal agglutinin test performed on the CSF is diagnostic of cryptococcosis.

Liposomal amphotericin B alone or in combination with flucytosine for 2 weeks is followed by oral fluconazole 400 mg daily. Therapy should be continued for 8 weeks if meningitis is present. Fluconazole has greater CSF penetration and is used when toxicity is encountered with amphotericin B and flucytosine and as maintenance therapy in immunocompromised patients, especially those with HIV infection (see p. 189).

Coccidioidomycosis

Coccidioidomycosis is caused by the non-budding spherical form (spherule) of *Coccidioides immitis*. This is a soil saprophyte and is found in the southern USA, Central America and parts of South America. Humans are infected by inhalation of the thick-walled barrel-shaped spores called arthrospores. Occasionally, epidemics of coccidioidomycosis have been documented following dust storms.

Clinical features

The majority of patients are asymptomatic and the infection is only detected by the conversion of a skin test using coccidioidin (extract from a culture of mycelial growth of *C. immitis*) from negative to positive. Acute pulmonary coccidioidomycosis presents, after an incubation period of about 10 days, with fever, malaise, cough and expectoration. Erythema nodosum, erythema multiforme, phlyctenular conjunctivitis and, less commonly, pleural effusions may occur. Complete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis, meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers and abscesses may occur in severe disease.

Diagnosis

The organism can be identified in respiratory secretions and can be cultured in specialist laboratories. Serological tests are also widely used for diagnosis. These include the highly specific latex agglutination and precipitin tests (IgM), which are positive within 2 weeks of infection and decline thereafter. Other tests include complement fixation, ELISA and radioimmunoassay.

A complement-fixation test (IgG) performed on the CSF is diagnostic of coccidioidomycosis meningitis and becomes positive within 4–6 weeks and remains so for many years.

Treatment

Mild pulmonary infections are self-limiting and require no treatment, but progressive and disseminated disease requires urgent therapy. Ketoconazole, itraconazole or fluconazole for 6 months is the treatment of choice for primary pulmonary disease with more prolonged courses for cavitating or

fibronodular disease. Fluconazole in high-dose (600–1000 mg daily) is given for meningitis. Itraconazole provides an alternative. Voriconazole and posaconazole are used for poor responders. Surgical excision of cavitary pulmonary lesions or localized bone lesions may be necessary.

Blastomycosis

Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis*. Although initially believed to be confined to certain parts of North America, it has been reported from South America, India and the Middle East.

Clinical features

Blastomycosis primarily involves the skin, where it presents as non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of tuberculosis. Systemic symptoms such as fever, malaise, cough and weight loss are usually present. Bone lesions are common and present as painful swellings.

Diagnosis and treatment

The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30–50% of cases. Enzyme immunoassay may be helpful although there is some cross-reactivity of antibodies to blastomyces with histoplasma.

Itraconazole is preferred for treating mild to moderate disease in the immunocompetent for periods up to 6 months. Ketoconazole or fluconazole are also used. In severe or unresponsive disease and in the immunocompromised, amphotericin B is indicated.

Mucormycosis

Invasive zygomycosis (mucormycosis) is rare and is caused by several fungi, including *Mucor* spp., *Rhizopus* spp. and *Absidia* spp. It occurs in severely ill patients. The hallmark of the disease is vascular invasion with marked haemorrhagic necrosis.

Rhinocerebral mucormycosis is the most common form. Nasal stuffiness, facial pain and oedema and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in diabetics with ketoacidosis.

Subcutaneous zygomycosis presents as a brawny, woody infiltration involving the limbs, neck and trunk and rarely the pharynx and orbital regions in immunosuppressed patients.

Other forms include pulmonary and disseminated infection (immunosuppressed) and gastrointestinal infection (in malnutrition).

Treatment is with amphotericin B and sometimes judicious debridement. Oral saturated potassium iodide has been used in the subcutaneous variety.

Subcutaneous infections**Sporotrichosis**

Sporotrichosis is caused by the saprophytic fungus *Sporothrix schenckii*, which is found worldwide. Infection usually

follows cutaneous inoculation, at the site of which a reddish, non-tender, maculopapular lesion develops – referred to as ‘plaque sporotrichosis’. Pulmonary involvement and disseminated disease rarely occur.

Treatment with itraconazole 100–200 mg/day for 3–6 months is usually curative.

Subcutaneous zygomycosis

Subcutaneous zygomycosis, a disease seen in the tropics, is caused by several filamentous fungi of the *Basidiobolus* genus. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck and trunk. Less commonly, the pharyngeal and orbital regions may be affected in immunocompromised patients and especially those with poorly controlled diabetes mellitus. It is locally erosive and can prove fatal. Amphotericin B is the drug of choice.

Treatment is with saturated potassium iodide solution given orally.

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is caused by fungi of various genera including *Phialophora*, *Wangella* and *Fonsecaea*. These are found mainly in tropical and subtropical countries. It presents initially as a small papule, usually at the site of a previous injury. This persists for several months before ulcerating. The lesion later becomes warty and encrusted and gradually spreads. Satellite lesions may be present. Itching is frequent. The drug of choice is amphotericin B in combination with itraconazole or voriconazole. Cryosurgery is used to remove local lesions.

Mycetoma (Madura foot)

Mycetoma may be due to subcutaneous infection with fungi (*Eumycetes* spp.) or bacteria (see p. 139). It is largely confined to the tropics. Infection results in local swelling which may discharge through sinuses. Bone involvement may follow.

Treatment consists of surgical debridement, combined with antimicrobials chosen according to the aetiological agent.

***Pneumocystis jiroveci* infection**

Genetic analysis has shown *P. jiroveci* to be homologous with fungi. *Pneumocystis jiroveci* disease is almost invariably associated with immunodeficiency states, particularly AIDS and is discussed on page 188.

Superficial infections**Dermatophytosis**

Dermatophytoses are chronic fungal infections of keratinous structures such as the skin, hair or nails. *Trichophyton* spp., *Microsporum* spp., *Epidermophyton* spp. and *Candida* spp. can also infect keratinous structures.

***Malassezia* infection**

Malassezia spp. are found on the scalp and greasy skin and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on trunk) and *Malassezia* folliculitis (itchy rash on back).

Treatment is with topical antifungals or oral ketoconazole if infection is refractory or more extensive.

PROTOZOAL INFECTIONS

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria and belong to the animal kingdom. Although many protozoa are free-living in the environment some have become parasites of vertebrates, including man, often developing complex life cycles involving more than one host species. In order to be transmitted to a new host, some protozoa transform into hardy cyst forms which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host.

Blood and tissue protozoa

Malaria

Human malaria is usually caused by one of four species of the genus *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*. Occasionally other species of malaria usually found in primates can affect man. Malaria probably originated from animal malarias in Central Africa, but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in most developed countries, although the potential for malaria transmission still exists in many areas. Some 400 million people are infected every year and over 1 million die annually; 25 000 international travellers per year are infected.

Epidemiology

Malaria is transmitted by the bite of female anopheline mosquitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect and its geographical range therefore depends on the presence of the appropriate mosquito species and an adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics except for some areas above

2000 m (Fig. 4.32). Australia, the USA and most of the Mediterranean littoral are also malaria-free. In *hyperendemic areas* (51–75% rate of parasitaemia or palpable spleen in children 2–9 years of age) and *holoendemic areas* (>75% rate) where transmission of infection occurs year round, the bulk of the mortality is seen in infants. Those who survive to adulthood acquire significant immunity; low-grade parasitaemia is still present, but causes few symptoms. In *mesoendemic areas* (11–50%), there is regular seasonal transmission of malaria. Mortality is still mainly seen in infants, but older children and adults may develop chronic ill health due to repeated infections. In *hypoendemic areas* (0–10%), where infection occurs in occasional epidemics, little immunity is acquired and the whole population is susceptible to severe and fatal disease.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in injecting drug users sharing needles and as a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas ('airport malaria'), or when the local mosquito population becomes infected by a returning traveller.

Parasitology

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial parasite (Fig. 4.33). The developmental cycle in the mosquito usually takes 7–20 days (depending on temperature), culminating in infective sporozoites migrating to the insect's salivary glands. The sporozoites are inoculated into a new human host and those which are not destroyed by the immune response are rapidly taken up by the liver. Here they multiply inside hepatocytes as merozoites: this is pre-erythrocytic (or hepatic) sporogony. After a few days, the infected hepatocytes rupture, releasing merozoites into the blood from where they are rapidly taken up by erythrocytes.

Table 4.38 Causes of anaemia in malaria infection

Haemolysis of infected red cells
Haemolysis of non-infected red cells (blackwater fever)
Dyserythropoiesis
Splenomegaly and sequestration
Folate depletion

In the case of *P. vivax* and *P. ovale*, a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

Inside the red cells, the parasites again multiply, changing from merozoite, to trophozoite, to schizont and finally appearing as 8–24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 h in *P. falciparum*, *P. vivax* and *P. ovale* and about 72 h in *P. malariae*. *P. vivax* and *P. ovale* mainly attack reticulocytes and young erythrocytes, while *P. malariae* tends to attack older cells; *P. falciparum* will parasitize any stage of erythrocyte.

A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red cells until taken up by a feeding mosquito to complete the life cycle.

Pathogenesis

The pathology of malaria is related to anaemia, cytokine release and in the case of *P. falciparum*, widespread organ damage due to impaired microcirculation. The anaemia seen in malaria is multifactorial (Table 4.38). In *P. falciparum* malaria, red cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver and other organs. As well as causing mechanical obstruction these schizonts rupture, releasing toxins and stimulating further cytokine release.

After repeated infections partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is largely lost if there is no further infection for a couple of years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria: this may account for the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection and splenectomized people are at risk of overwhelming malaria. Some individuals appear to have a genetic predisposition for developing cerebral malaria following infection with *P. falciparum*. Pregnant women are especially susceptible to severe disease.

Clinical features

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in hypoendemic areas and any visitors from a non-malarious region.

The normal incubation period is 10–21 days, but can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting, or diarrhoea. At first, the fever may be continual or erratic: the classical tertian or quartan fever only appears after some days. The temperature often reaches 41°C and is accompanied by rigors and drenching sweats.

P. vivax or *P. ovale* infection

The illness is usually relatively mild (although *P. vivax* can occasionally cause severe disease). Anaemia develops slowly and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2–6 weeks, but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health due to anaemia and hyperreactive splenomegaly.

P. malariae infection

This also causes a relatively mild illness, but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, *P. malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

P. falciparum infection

This causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However, it may also cause serious complications (Box 4.14) and the vast majority of malaria deaths are due to *P. falciparum*. Patients can deteriorate rapidly and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (>1% of red cells infected) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications. *Cerebral malaria* is marked by diminished consciousness, confusion and convulsions, often progressing to coma and death. Untreated it is universally fatal. *Blackwater fever* is due to widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine.

Hyperreactive malarial splenomegaly (tropical splenomegaly syndrome, TSS)

This is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an

exaggerated immune response to repeated malaria infections and is characterized by anaemia, massive splenomegaly and elevated IgM levels. Malaria parasites are scanty or absent. TSS usually responds to prolonged treatment with prophylactic antimalarial drugs.

Diagnosis

Malaria should be considered in the differential diagnosis of anyone who presents with a febrile illness in, or having

recently left, a malarious area. Falciparum malaria is unlikely to present more than 3 months after exposure, even if the patient has been taking prophylaxis, but vivax malaria may cause symptoms for the first time up to a year after leaving a malarious area.

Diagnosis is usually made by identifying parasites on a Giemsa-stained thick or thin blood film (thick films are more difficult to interpret and it may be difficult to speciate the parasite, but they have a higher yield). At least three films should be examined before malaria is declared unlikely. Rapid antigen detection tests are available for near-patient use. In many endemic areas, malaria is overdiagnosed on clinical grounds and a definite diagnosis should be made wherever possible. Serological tests are of no diagnostic value.

Parasitaemia is common in endemic areas and the presence of parasites does not necessarily mean that malaria is the cause of the patient's symptoms. Further investigation, including a lumbar puncture, may be needed to exclude bacterial infection.

Management

Treatment of uncomplicated malaria. The drug of choice for **susceptible** parasites is chloroquine (Box 4.15). *P. vivax*, *P. ovale* and *P. malariae* are usually sensitive to this drug, although there is increasing resistance in some strains of *P. vivax*. Following successful treatment of *P. vivax* or *P. ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (15 mg daily) to eradicate the hepatic hypnozoites and prevent relapse. This drug can precipitate haemolysis in patients with G6PD deficiency (see p. 396).

The artemisinin-based drugs are the most effective treatment for both uncomplicated and severe infections with *P. falciparum*, in adults and in children. Artemisinin-based combination therapy (ACT) is the recommended oral treatment for uncomplicated falciparum malaria worldwide. These drugs are now quite widely available, partly through the efforts of the Global Fund (www.theglobalfund.org). Five different fixed-dose combinations are recommended by the WHO (Box 4.16); the choice should be based on local resistance to the 'partner' drug. Artemisinin derivatives should not

Box 4.14 Some features of severe falciparum malaria

CNS

- Prostration
- Cerebral malaria (coma convulsion = 3 seizures in 24 h)

Renal

- Haemoglobinuria (blackwater fever)
- Oliguria
- Uraemia (serum creatinine >250 µmol/L) (acute tubular necrosis)

Blood

- Severe anaemia (<50 g/L) (haemolysis and dyserythropoiesis)
- Disseminated intravascular coagulation (DIC)
- Bleeding, e.g. retinal haemorrhages

Respiratory

- Tachypnoea
- Acute respiratory distress syndrome

Metabolic

- Hypoglycaemia (<2 mmol/L) (particularly in children)
- Metabolic acidosis (blood pH <7.25)

Gastrointestinal/liver

- Diarrhoea
- Jaundice (bilirubin >50 µmol/L)
- Splenic rupture

Other

- Shock – hypotensive (<80 systolic pressure) and Gram-negative septicaemia
- Hyperpyrexia

Smithuis F, Kyaw MK, Phe O et al. Effectiveness of five artemisinin combination regimens with or without primaquine in uncomplicated falciparum malaria: an open-label randomised trial. *Lancet Infect Dis* 2010; 10:673–681.

be given as monotherapy, to limit resistance which has already occurred in Cambodia. The WHO recommends that a single dose of primaquine should be given as a gametocide, to decrease transmission.

Treatment of severe falciparum malaria. Severe malaria, indicated by the presence of any of the complications discussed above, or a parasite count above 1% in a non-immune patient, is a medical emergency (Emergency Box 4.1). Anyone involved in managing patients with malaria should be familiar with the latest WHO guidelines.

- Intravenous artesunate is more effective than intravenous quinine and should be used where available. Absorption from intramuscular injection is less reliable than from intravenous injection.
- Intensive care facilities may be needed, including mechanical ventilation and dialysis.
- Severe anaemia may require transfusion.

Box 4.16 Suitable artemisinin combination therapies (ACT) for malaria

Fixed-dose combination tablets available

Artemether-lumefantrine	4 tablets twice daily for 3 days ^a
Artesunate-amodiaquine	4 mg/kg per day artesunate for 3 days
Dihydroartemisinin-piperaquine	4 mg/kg per day dihydroartemisinin for 3 days

Available as fixed-dose co-packaged separate tablets

Artesunate-mefloquine ^b	4 mg/kg per day artesunate for 3 days
Artesunate-sulfadoxine-pyrimethamine ^c	4 mg/kg per day artesunate for 3 days

Alternatives where no combination packages are available

Artesunate + clindamycin	2 mg/kg per day + 10 mg/kg twice daily for 7 days
Artesunate + doxycycline	2 mg/kg per day + 3.5 mg/kg per day for 7 days

^aAdult dose: reduce dose by body weight for children;

^bCombination tablet available soon; ^cNot suitable for *P. vivax* or mixed infections. Different fixed-dose combinations available.

- Careful monitoring of fluid balance is essential: both pulmonary oedema and prerenal failure are common.
- Hypoglycaemia can be induced both by the infection itself and by quinine treatment.
- Superadded bacterial infection is common.

In very heavy infections (parasitaemia >10%), there may be a role for exchange transfusion, if the facilities are available.

Prevention and control

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication and personal protection from vector bites, e.g. insecticide (permethrin) treated nets. Mosquito eradication is usually achieved either by the use of insecticides, house spraying with DDT or by manipulation of the habitat (e.g. marsh drainage). After some initial successes, a WHO campaign to eliminate malaria foundered in the mid-1960s. Since then, the emergence of both parasite resistance to drugs and mosquito resistance to insecticides has rendered the task more difficult. However, malaria is once again a priority for the WHO, which announced a new 'Roll Back Malaria' campaign in 1998. This has had good success in some countries who have coordinated programmes, including the use of insecticide-treated bed nets and indoor residual spraying with DDT. A 3-part strategy is now widely endorsed and supported by governments and non-governmental organizations (Box 4.17).

Non-immune travellers to malarious areas should take measures to avoid insect bites, such as using insect repellent (diethyltoluamide, DEET, 20–50% in lotions and sprays) and sleeping under mosquito nets. Antimalarial prophylaxis should also be taken in most cases, although this is never

Box 4.17 Strategy for controlling malaria

1. Aggressive control in highly endemic countries, to reduce mortality and decrease transmission
2. Progressive eradication at the endemic margins, to shrink the 'malaria map'
3. Research into new vaccines, new drugs, new diagnostics and better ways of delivering malaria care

**Emergency Box 4.1****Drug treatment of severe falciparum malaria in adults and children**

Severe malaria is an emergency: after rapid assessment and confirmation of diagnosis if possible, treatment should be started with whatever parenteral treatment is available. The options, in order of preference, are:

	Immediate dose	Subsequent doses
1. Intravenous artesunate	2.4 mg/kg	2.4 mg/kg at 12 and 24 h, then daily (up to 7 days)
2. Intravenous quinine	20 mg/kg ^a	10 mg/kg 8 hourly (up to 7 days)
3. Intramuscular artesunate	2.4 mg/kg	2.4 mg/kg at 12 and 24 h, then daily (up to 7 days)
4. Intramuscular artemether	3.2 mg/kg	1.6 mg/kg daily
5. Rectal artesunate	10 mg/kg	Transfer to centre where parenteral therapy available
Continue parenteral treatment for at least 24 h, regardless of improvement in condition. After this, if patient improving, switch to oral therapy to complete 7 days with:		
ACT Or Quinine + doxycycline	Plus	Primaquine 0.75 mg/kg single dose

^a10 mg/kg if patient has already received oral quinine or mefloquine.

Box 4.18 Malaria prophylaxis for adult travellers

Area visited	Prophylactic regimen	Alternative
No chloroquine resistance	Chloroquine 300 mg weekly	Proguanil 200 mg daily
Limited chloroquine resistance	Chloroquine 300 mg weekly plus Proguanil 200 mg daily	Doxycycline 100 mg daily or Malarone 1 tablet daily or Mefloquine 250 mg weekly
Significant chloroquine resistance	Mefloquine 250 mg weekly	Doxycycline 100 mg daily or Malarone 1 tablet daily

100% effective (Box 4.18). The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in National Formularies or from travel advice centres. Despite considerable efforts, there is still no effective vaccine available for malaria.

Trypanosomiasis

African trypanosomiasis (sleeping sickness)

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (genus *Glossina*). It is endemic in a belt across sub-Saharan Africa, extending to about 14°N and 20°S: this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: *Trypanosoma bruceigambiense* ('Gambian sleeping sickness') and *T. b. rhodesiense* ('Rhodesian sleeping sickness').

Epidemiology

Sleeping sickness due to *T. b. gambiense* is found from Uganda in Central Africa, west to Senegal and south as far as Angola. Man is the major reservoir and infection is transmitted by riverine *Glossina* species (e.g. *G. palpalis*).

Sleeping sickness due to *T. b. rhodesiense* occurs in East and Central Africa from Ethiopia to Botswana. It is a zoonosis of both wild and domestic animals. In endemic situations it is maintained in game animals and transmitted by savanna flies such as *G. morsitans*. Epidemics are usually related to cattle and the vectors are riverine flies.

Political upheavals during the 1990s disrupted established treatment and control programmes, resulting in major epidemics in the Republic of Angola, the Democratic Republic of Congo (DRC) and Uganda. By 1997 as many as 500 000 people were affected by sleeping sickness. A concerted control programme has brought this number down to below 30 000, most of which are in DRC and the Central African Republic.

Parasitology

Tsetse flies bite during the day and unlike most arthropod vectors both males and females take blood meals. An infected insect may deposit metacyclic trypomastigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation ('trypanosomal chancre') and regional lymphadenopathy. Within 2–3 weeks the organisms invade the bloodstream, subsequently spreading to all parts of the body including the brain.

Box 4.19 Drugs used in the treatment of African trypanosomiasis

	<i>T. b. gambiense</i>	<i>T. b. rhodesiense</i>
Stage 1	Pentamidine	Suramin ^a
Stage 2 (CNS)	Eflornithine + nifurtimox Eflornithine monotherapy (melarsoprol)	Melarsoprol

^aSevere allergic reactions common: give test dose.

Clinical features

T. b. gambiense causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years and hepatosplenomegaly may develop. Eventually infection reaches the central nervous system, causing headache, behavioural changes, confusion and daytime somnolence. As the disease progresses patients may develop tremors, ataxia, convulsions and hemiplegias; eventually coma and death supervene. Histologically there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

T. b. rhodesiense sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis and serous effusions and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection and is rapidly progressive.

Diagnosis

Trypanosomes may be seen on Giemsa-stained smears of thick or thin blood films, or of lymph node aspirate. Blood films are usually positive in *T. b. rhodesiense*, but may be negative in *T. b. gambiense*: concentration techniques may increase the yield. Serological tests are useful for screening for infection: the card agglutination test for trypanosomiasis (CATT) is a robust and easy-to-use field assay. Examination of cerebrospinal fluid is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF and parasites may be seen in concentrated specimens.

Management

The treatment of sleeping sickness had remained largely unchanged for more than 40 years, but there have been recent improvements in the management of *T. b. gambiense* infection. In both forms, treatment is usually effective if given before the onset of CNS involvement (Box 4.19). A single dose of suramin should be given to patients with parasitaemia prior to lumbar puncture, to avoid inoculation into the CSF. The treatment of choice for 2nd stage (CNS) disease in *T. b. gambiense* is a combination of eflornithine and nifurtimox, a therapy introduced in 2009 and provided free via the WHO. Melarsoprol remains the only treatment for CNS infection with *T. b. rhodesiense*. It is extremely toxic: 2–10% of patients develop an acute encephalopathy, with a 50–75% mortality; peripheral neuropathy and hepatorenal toxicity are also common. Between 3% and 6% of patients relapse following melarsoprol treatment.

Control

Control programmes coordinated by WHO have been effective in many areas. As in many vector-borne diseases, prevention depends largely on elimination, control, or avoidance of the vector.

Maguire JH. Chagas disease – can we stop the deaths? *N Engl J Med* 2006; 355:760–761.

South American trypanosomiasis (Chagas' disease)

Chagas' disease is widely distributed in rural areas of South and Central America, where up to 10 million people are infected. It is caused by *Trypanosoma cruzi*, which is transmitted to humans in the faeces of bloodsucking reduviid bugs (also called cone-nose or assassin bugs). Faeces infected with *T. cruzi* trypomastigotes are rubbed in through skin abrasions, mucosa or conjunctiva. The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts (e.g. rats, opossums) at night, defecating as they do so.

The parasites spread in the bloodstream, before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug. Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion, or occasionally by transplacental spread.

Clinical features

Acute infection, which usually occurs in children, often passes unnoticed. A firm reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection there is swelling of the eyelid, which may close the eye (Romaña's sign). There may be fever, lymphadenopathy, hepatosplenomegaly and rarely meningoencephalitis. Acute Chagas' disease is occasionally fatal in infants, but normally there is full recovery within a few weeks or months.

Chronic Chagas' disease. 10–30% of people go on to develop *chronic Chagas' disease* after a latent period of many years. The pathogenesis of this is unclear: it is possibly due to an autoimmune response triggered by the initial infection, although recent evidence has thrown doubt on this mechanism. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation and cardiac dilatation. Gastrointestinal involvement leads to progressive dilatation of parts of the gastrointestinal tract: this commonly results in megaoesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

Diagnosis

Trypanosomes may be seen on a stained blood film during the acute illness. In chronic disease, parasites may be detected by xenodiagnosis: infection-free reduviid bugs are allowed to feed on the patient and the insect gut subsequently examined for parasites. Serological tests can detect both acute and chronic Chagas' disease.

Management and control

Nifurtimox and benznidazole are the main drugs used in Chagas' disease. Both are highly effective in acute infection, with a cure rate of over 90%, but much less so in chronic disease. They are relatively toxic with adverse reactions in up to 40% of patients and new drugs are urgently needed. Antiarrhythmic drugs and pacemakers may be needed in cardiac disease and surgical treatment is sometimes needed for gastrointestinal complications.

In the long term, prevention of Chagas' disease relies on improved housing and living conditions. In the interim, local vector control programmes may be effective and the countries of the 'Southern Cone' of South America run a successful joint programme to control the disease by spraying houses with insecticide. Impregnated bed nets with pyrethroid and insect repellents should be used.

Table 4.39 *Leishmania* species causing visceral and cutaneous disease in man

	Species complex	Species

Cutaneous leishmania	<i>L. tropica</i> <i>L. major</i> <i>L. aethiopica</i> <i>L. mexicana</i>	<i>L. tropica</i> <i>L. major</i> <i>L. aethiopica</i> <i>L. mexicana</i> <i>L. amazonensis</i> <i>L. garnhami</i> <i>L. pifanoi</i> <i>L. venezuelensis</i> <i>L. braziliensis</i> <i>L. guyanensis</i> <i>L. panamanensis</i> <i>L. peruviana</i>
Mucocutaneous leishmania	<i>L. braziliensis</i>	<i>L. braziliensis</i>

Leishmaniasis

This group of diseases is caused by protozoa of the genus *Leishmania*, which are transmitted by the bite of the female phlebotomine sandfly (Table 4.39). Leishmaniasis is seen in localized areas of Africa, Asia (particularly India and Bangladesh), Europe, the Middle East and South and Central America. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite and on the host's cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas, as demonstrated by a high incidence of positive leishmanin skin tests. Symptomatic infection may be confined to the skin (sometimes with spread to the mucous membranes) or widely disseminated throughout the body (visceral leishmaniasis). Relapse of previously asymptomatic infection is seen in patients who become immunocompromised, especially those with HIV infection.

In some areas, leishmania is primarily zoonotic, whereas in others, man is the main reservoir of infection. In the vertebrate host the parasites are found as oval amastigotes (Leishman–Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus *Phlebotomus* in the Old World, genus *Lutzomyia* in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

Visceral leishmaniasis

Clinical features

Visceral leishmaniasis (kala azar) is caused by *L. donovani*, *L. infantum*, or *L. chagasi* and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral and South America. In parts of India, where man is the main host, the disease occurs in epidemics. In most other areas it is endemic and it is mainly children and visitors to the area who are at risk. The main animal reservoirs in Europe and Asia are dogs and foxes, while in Africa it is carried by various rodents.

The incubation period is usually 1–2 months, but may be several years. The onset of symptoms is insidious and the patient may feel quite well despite markedly abnormal physical findings. Fever is common and although usually low-grade, it may be high and intermittent. The liver and especially

the spleen, become enlarged; lymphadenopathy is common in African kala azar. The skin becomes rough and pigmented. If the disease is not treated, profound pancytopenia develops and the patient becomes wasted and immunosuppressed. Death usually occurs within a year and is normally due to bacterial infection or uncontrolled bleeding.

Diagnosis

Specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen or liver. The organism can also be cultured from these specimens. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia and hypergamma-globulinaemia are common. The leishmanin skin test is negative, indicating a poor cell-mediated immune response.

Management

The most widely used drugs for visceral leishmaniasis are the pentavalent antimony salts (e.g. sodium stibogluconate and meglumine antimoniate). Resistance to antimony salts is increasing and relapses may occur following treatment. Intravenous amphotericin B (preferably liposomal, which may be curative as a single dose treatment) is effective but expensive; intramuscular paromomycin is cheaper and also has a good cure rate. An oral drug, miltefosine, has been shown in India to be highly effective and may replace older therapies. There is currently considerable interest in the use of combination therapy to shorten treatment courses and limit resistance.

Successful treatment may be followed in a small proportion of patients by a skin eruption called *post-kala azar dermal leishmaniasis* (PKDL). It starts as a macular maculopapular nodular rash which spreads over the body. It is most often seen in the Sudan and India. There have been reports of PKDL responding to miltefosine.

Cutaneous leishmaniasis

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthroponotic. Following a sandfly bite, leishmania amastigotes multiply in dermal macrophages. The local response depends on the species of leishmania, the size of the inoculum and the host immune response. Single or multiple painless nodules occur on exposed areas within 1 week to 3 months following the bite. These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

L. major and *L. tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral and sub-Saharan Africa. The reservoir for *L. major* is desert rodents, while *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs. *L. aethiopica* is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions usually heal spontaneously with scarring: this may take a year or more in the case of *L. tropica*. Leishmaniasis recidivans is a rare chronic relapsing form caused by *L. tropica*.

L. mexicana is found predominantly in Mexico, Guatemala, Brazil, Venezuela and Panama; infection usually runs a benign course with spontaneous healing within 6 months. *L. braziliensis* infections (which are seen throughout tropical South America) also usually heal spontaneously, but may take longer.

L. mexicana amazonensis and *L. aethiopica* may occasionally cause diffuse cutaneous leishmaniasis. This is rare and

is characterized by diffuse infiltration of the skin by Leishman-Donovan bodies. Visceral lesions are absent.

Diagnosis and treatment

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin smear will demonstrate leishmania parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically and parasites identified by PCR; culture is less often successful. The leishmanin skin test is positive in over 90% of cases, but does not distinguish between active and resolved infection. Serology is unhelpful.

Small lesions usually require no treatment. Large lesions or those in cosmetically sensitive sites can sometimes be treated locally, by curettage, cryotherapy or topical antiparasitic agents. In other cases, systemic treatment (as for visceral leishmaniasis) is required.

Mucocutaneous leishmaniasis

Mucocutaneous leishmaniasis occurs in 3–10% of infections with *L. b. braziliensis* and is commonest in Bolivia and Peru. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose ('espundia'). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate and upper airways.

Diagnosis and treatment

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; serological tests are frequently positive.

Amphotericin B is the treatment of choice if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common following treatment. Patients may die because of secondary bacterial infection, or occasionally laryngeal obstruction.

Prevention

Prevention of leishmaniasis relies on control of vectors and/or reservoirs of infection. Insecticide spraying, control of host animals and treating infected humans may all be helpful. Personal protection against sandfly bites is also necessary, especially in travellers visiting endemic areas. Sandflies are poor fliers and sleeping off the ground helps prevent bites.

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii*. The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source of infection for secondary hosts which may ingest them. In the secondary hosts (which include man, cattle, sheep, pigs, rodents and birds), there is disseminated infection. Following a successful immune response the infection is controlled, but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces, or by eating undercooked infected meat; transplant infection may also occur.

Clinical features

Toxoplasmosis is common: seroprevalence in adults in the UK is about 25%, rising to 90% in some parts of Europe.

van Griensven J, Boelaert M. Combination therapy for visceral leishmaniasis. *Lancet* 2011; 377:443–444.

Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia and general malaise; occasionally there are more severe manifestations including hepatitis, pneumonia, myocarditis and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic, but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions and mental retardation. Choroidoretinitis is common; occasionally this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii*. In acquired immunodeficiency states this is usually due to reactivation of latent disease (see p. 189).

Diagnosis

Diagnosis is usually made serologically. IgG antibodies detectable by the Sabin–Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a rising titre of specific IgM.

Management

Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement) sulfadiazine 2–4 g daily and pyrimethamine 25 mg daily are given for 4 weeks, along with folinic acid. The management of pregnant women with toxoplasmosis aims to decrease the risk of fetal complications. However, there is little good evidence that giving spiramycin either alone or in combination with sulfadiazine (which is the recommended treatment) has any significant effect on the frequency or severity of fetal damage. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered on page 189.

Babesiosis

Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle and is occasionally transmitted to humans: infection is more common and more severe in those who are immunocompromised following splenectomy. The causative organisms are the plasmodium-like *Babesia microti* (rodents) and *B. divergens* (cattle).

The incubation period averages 10 days. In patients with normal splenic function, the illness is usually mild. In splenectomized individuals, systemic symptoms are more pronounced and haemolysis is associated with haemoglobinuria, jaundice and acute kidney injury (AKI). Examination of a peripheral blood smear may reveal the characteristic plasmodium-like organisms.

The standard treatment of severe babesiosis is a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days. Atovaquone and azithromycin plus doxycycline is used for persistent or relapsing disease.

Gastrointestinal protozoa

The major gastrointestinal parasites of man are shown in Table 4.40.

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica*. The organism formerly known as *E. histolytica* is known to consist of three distinct species: *E. histolytica*, which is pathogenic,

Table 4.40 Pathogenic human intestinal protozoa

Amoebae
<i>Entamoeba histolytica</i>
Flagellates
<i>Giardia intestinalis</i>
Ciliates
<i>Balantidium coli</i>
Coccidia
<i>Cryptosporidium parvum</i>
<i>Isospora belli</i>
<i>Sarcocystis</i> spp.
<i>Cyclospora cayetanensis</i>
Microspora
<i>Enterocytozoon bieneusi</i>
<i>Encephalitozoon</i> spp.

E. dispar, which is non-pathogenic, and *E. moshkovskii*, which is of uncertain significance. Cysts of the three species are identical, but can be distinguished by molecular techniques after culture of the trophozoite. *E. histolytica* can be distinguished from all other amoebae and from other intestinal protozoa, by microscopic appearance. Amoebiasis occurs worldwide, although much higher incidence rates are found in the tropics and subtropics.

The organism exists both as a motile trophozoite and as a cyst that can survive outside the body. Cysts are transmitted by ingestion of contaminated food or water, or spread directly by person-to-person contact. Trophozoites emerge from the cysts in the small intestine and then pass on to the colon, where they multiply.

Clinical features

It is believed that many individuals can carry the pathogen without obvious evidence of clinical disease (asymptomatic cyst passers). However, this may be due in some cases to the misidentification of non-pathogenic *E. dispar* as *E. histolytica* and it is not clear how often true *E. histolytica* infection is symptomless. In affected people *E. histolytica* trophozoites invade the colonic epithelium, probably with the aid of their own cytotoxins and proteolytic enzymes. The parasites continue to multiply and finally frank ulceration of the mucosa occurs. If penetration continues, trophozoites may enter the portal vein, via which they reach the liver and cause intra-hepatic abscesses. This invasive form of the disease is serious and may even be fatal.

The incubation period of intestinal amoebiasis is highly variable and may be as short as a few days or as long as several months. The usual course is chronic, with mild intermittent diarrhoea and abdominal discomfort. This may progress to bloody diarrhoea with mucus and is sometimes accompanied by systemic symptoms such as headache, nausea and anorexia. Less commonly, infection may present as acute amoebic dysentery, resembling bacillary dysentery or acute ulcerative colitis.

Complications are unusual, but include toxic dilatation of the colon, chronic infection with stricture formation, severe haemorrhage, amoeboma and amoebic liver abscess. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever and profound malaise are characteristic, although early in the course of the disease both symptoms and signs may be minimal. The clinical features are described in more detail on page 345.

Diagnosis

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy is the simplest way of diagnosing

colonic amoebic infection. To confirm the diagnosis motile trophozoites containing red blood cells must be identified: the presence of amoebic cysts alone does not imply disease. Sigmoidoscopy and barium enema examination may show colonic ulceration but are rarely diagnostic.

The amoebic fluorescent antibody test is positive in at least 90% of patients with liver abscess and in 60–70% with active colitis. Seropositivity is low in asymptomatic cyst passers.

Management

Metronidazole 800 mg three times daily for 5 days is given in amoebic colitis; a lower dose (400 mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective. After treatment of the invasive disease, the bowel should be cleared of parasites with a luminal amoebicide such as diloxanide furoate.

Prevention

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. The only progress will be through improved standards of hygiene, sanitation and better access to clean water. Cysts are destroyed by boiling, but chlorine and iodine sterilizing tablets are not always effective.

Giardiasis

Giardia intestinalis is a flagellate (Fig. 4.34) that is found worldwide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high in many developing countries and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe and in some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions. The organism exists both as a trophozoite and a cyst, the latter being the form in which it is transmitted.

The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host.

Figure 4.34 *Giardia intestinalis* on small intestinal mucosa. (Courtesy of Dr A Phillips, Department of Electron Microscopy, Royal Free Hospital, London.)

In other cases, severe malabsorption may occur which is thought to be related to morphological damage to the small intestine. The changes in villous architecture are usually mild partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal malabsorption is unknown: there is evidence that the morphological damage is immune-mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

Clinical features

Many individuals excreting *Giardia* cysts have no symptoms. Others become ill within 1–3 weeks after ingesting cysts: symptoms include diarrhoea, often watery in the early stage of the illness, nausea, anorexia and abdominal discomfort and bloating. In most people affected these symptoms resolve after a few days, but in some they persist. Stools may then become paler, with the characteristic features of steatorrhoea. If the illness is prolonged, weight loss, which can be marked, occurs. Chronic giardiasis frequently seen in developing countries can result in growth retardation in children.

Diagnosis

Both cysts and trophozoites can be found in the stool, but negative stool examination does not exclude the diagnosis since the parasite may be excreted at irregular intervals. The parasite can also be seen in duodenal aspirates (obtained either at endoscopy or with a luminal capsule) and in histological sections of jejunal mucosa.

Management

Metronidazole 2 g as a single dose on three successive days will cure the majority of infections, although sometimes a second or third course is necessary. Alternative drugs include tinidazole, mepacrine and albendazole. Preventative measures are similar to those outlined above for *E. histolytica*.

Cryptosporidiosis

This organism is found worldwide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals cryptosporidiosis is a self-limiting illness. Acute watery diarrhoea is associated with fever and general malaise lasting for 7–10 days. In immunocompromised patients, especially those with HIV, diarrhoea is severe and intractable (see p. 189).

Diagnosis is usually made by faecal microscopy, although the parasite can also be detected in intestinal biopsies. There is no reliable treatment, although nitazoxanide may be of benefit.

Balantidiasis

Balantidium coli is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea and the Philippines. It is usually carried by pigs and infection is most common in those communities that live in close association with swine. Its life cycle is identical to that of *E. histolytica*. *B. coli* causes diarrhoea and sometimes a dysenteric illness with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

Farthing MJ. Treatment options for the eradication of intestinal protozoa. *Nat Clin Pract Gastroenterol Hepatol* 2006; 3:436–445.

Blastocystis hominis infection

B. hominis is a strictly anaerobic protozoan pathogen that inhabits the colon. The pathogenicity for humans remains controversial despite many studies indicating response to chemotherapy.

Cyclospora cayetanensis infection

Cyclospora cayetanensis, a coccidian protozoal parasite, was originally recognized as a cause of diarrhoea in travellers

to Nepal. It has been detected in stool specimens from immunocompetent and immunodeficient people worldwide. Infection is usually self-limiting, but can be treated with co-trimoxazole.

Microsporidiosis

Protozoa of the phylum *Microsporea* can cause diarrhoea in patients with HIV/AIDS (see p. 190).

HELMINTHIC INFECTIONS

Worm infections are very common in developing countries, causing much disease in both humans and domestic animals. Worms are frequently imported into industrialized countries. The most common human helminth infections are listed in Table 4.41. Three in particular – ascariasis, hookworm and trichuriasis – are included in a list of 13 ‘neglected tropical diseases’, which the WHO has identified as causing major disability among the poorest people in the world.

Helminths are the largest internal human parasite. They reproduce sexually, generating millions of eggs or larvae. *Nematodes* and *trematodes* have a mouth and intestinal tract, while *cestodes* absorb nutrients directly through the outer tegument. All worms are motile, although once the adults are established in their definitive site, they rarely migrate further. Adult helminths may be very long-lived: up to 30 years in the case of the schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate

hosts are often highly specific to a particular species of worm. In some cases of human infection man is the primary host, while in others humans are a nonspecific intermediary or are coincidentally infected. Multiple infections with different helminths are common in endemic areas. Mass treatment programmes, in which one or more anthelmintic drugs are given on a regular (usually annual) basis, are used to keep the total worm load down (Table 4.42).

Nematodes

Human infections can be divided into:

- Tissue-dwelling worms, including the filarial worms and the Guinea worm *Dracunculus medinensis*
- Human intestinal worms, including the human hookworms, the common roundworm (*Ascaris lumbricoides*) and *Strongyloides stercoralis*, which are

Table 4.41 Helminths commonly infecting man

Larval tissue cysts	<i>Taenia solium</i> <i>Echinococcus granulosus</i> <i>Echinococcus multilocularis</i> <i>Spirometra mansoni</i>	Cysticercosis Hydatid disease Hydatid disease Sparganosis

the most common helminthic parasites of man. The adult worms live in the human gut and do not usually invade tissues, but many species have a complex life cycle involving a migratory larval stage

- Zoonotic nematodes, which accidentally infect man and are not able to complete their normal life cycle. They often become 'trapped' in the tissues, causing a potentially severe local inflammatory response.

Tissue-dwelling worms

Filariasis

Several nematodes belonging to the superfamily Filarioidea can infect humans. The adult worms are long and threadlike, ranging from 2 cm to 50 cm in length; females are generally much larger than males. Larval stages are inoculated into humans by various species of biting flies (each specific to a particular parasite). The adult worms which develop from these larvae mate, producing millions of offspring (microfilariae), which migrate in the blood or skin. These are ingested by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused by either the adult worms or by microfilariae, is caused by host immune response to the parasite and is characterized by massive eosinophilia. Adult worms are long-lived (10–15 years) and reinfection is common, so that disease tends to be chronic and progressive.

Lymphatic filariasis

Lymphatic filariasis, which may be caused by different species of filarial worm, has a scattered distribution in the tropics and subtropics (Table 4.43). More than 1 billion people in developing countries are at risk. *Wuchereria bancrofti* is transmitted to man by a number of mosquito species,

mainly *Culex fatigans*. Adult female worms (which are 5–10 cm long) live in the lymphatics, releasing large numbers of microfilariae into the blood. Generally this occurs at night, coinciding with the nocturnal feeding pattern of *C. fatigans*. Non-periodic forms of *W. bancrofti*, transmitted by day-biting species of mosquito, are found in the South Pacific. *Brugia malayi* (and the closely related *B. timori*) are very similar to *W. bancrofti*, exhibiting the same nocturnal periodicity. The usual vectors are mosquitoes of the genus *Mansonia*, although other mosquitoes have been implicated.

Many filarial worms co-exist with symbiotic *Wolbachia* bacteria, which are in themselves a cause of inflammation in the human host.

Clinical features

Following the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. Here, they grow and mature for 6–18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as age at first exposure. In endemic areas many people have asymptomatic infection. Sometimes early infection is marked by bouts of fever accompanied by pain, tenderness and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis are common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days, but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible. Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous pleural effusions and ascites. Over time, there is progressive enlargement, coarsening and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually, the adult worms will die, but the lymphatic obstruction remains and tissue damage continues. Elephantiasis takes many years to develop and is only seen in association with recurrent infection in endemic areas.

Occasionally the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as *tropical pulmonary eosinophilia* (see p. 853).

Diagnosis

The clinical picture in established disease is usually diagnostic, although similar lymphatic damage may occasionally be

caused by silicates absorbed through the feet from volcanic soil (podoconiosis). Parasitological diagnosis has traditionally relied on detecting microfilariae in blood films or skin snips, but rapid and sensitive near-patient antigen detection tests are now available.

Treatment

Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed and particular care is needed when using DEC in areas endemic for loiasis. Mass treatment programmes using combinations of DEC, ivermectin and albendazole to target various helminthic infections are used in many parts of the world: the exact regimens depend on local situations (see 'Further Reading'). Over 500 million people have already received such treatment. There is currently much interest in using doxycycline to kill the symbiotic *Wolbachia* bacteria, without which the adult worm will eventually die. However, the best way of incorporating this into the overall management strategy remains unclear.

Loiasis

Loiasis is found in the humid forests of West and Central Africa. The causative parasite, *Loa loa*, is a small (3–7 cm) filarial worm, which is found in the subcutaneous tissues. The microfilariae circulate in the blood during the day, but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops*.

Adult worms migrate around the body in subcutaneous tissue planes. Worms may be present for years, frequently without causing symptoms. From time to time localized, tender, hot, soft tissue swellings occur due to hypersensitivity (Calabar swellings) often near to a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally, a worm may be seen crossing the eye under the conjunctiva; they may also enter retro-orbital tissue, causing severe pain. Short-term residents of endemic areas often have more severe manifestations of the disease.

Microfilariae may be seen on stained blood films, although these are often negative. Serological tests are relatively insensitive and cross-react with other microfilariae. There is usually massive eosinophilia. DEC may cause severe allergic reactions associated with parasite killing and is being replaced by newer agents. Ivermectin in single doses of 200–400 µg/kg is effective: it may occasionally cause severe reactions. Albendazole, which causes a more gradual reduction in microfilarial load, may be preferable in heavily-infected patients. Mass treatment with either DEC or ivermectin can decrease the transmission of infection, but the mainstay of prevention is vector avoidance and control.

Onchocerciasis

Onchocerciasis (river blindness) affects 37 million people worldwide, of whom 250 000 are blind and 500 000 visually impaired; most of these are in West and Central Africa, with small foci in the Yemen and Central and South America. It is the result of infection with *Onchocerca volvulus*. Infection is transmitted by day-biting flies of the genus *Simulium*.

Pathogenesis

Infection occurs when larvae are inoculated into humans by the bite of an infected fly. The worms mature in 2–4 months and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although <0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules,

especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin and may invade the eyes. Live microfilariae cause relatively little harm, but dead parasites may cause severe allergic reactions, with hyaline necrosis and loss of tissue collagen and elastin. In the eye a similar process causes conjunctivitis, sclerosing keratitis, uveitis and secondary glaucoma. Choroidoretinitis is also occasionally seen.

Clinical features

Symptoms usually start about a year after infection. Initially, there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasound) start to appear and in dark-skinned individuals, hypo- and hyperpigmentation from excoriation and inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged and in the groin may hang down in loose folds of skin ('hanging groin'). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness.

Diagnosis

In endemic areas, the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. In order to identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing: this will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction) but this is not routinely performed as it is unpleasant. Slit-lamp examination of the eyes may reveal the microfilariae. Rapid serological tests are being developed.

Management and prevention

Ivermectin, in a single dose of 150 µg/kg, kills microfilariae and prevents their return for 6–12 months. There is little effect on adult worms, so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa*, ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy.

Since 1974, the WHO Onchocerciasis Control Programme has had a considerable impact on onchocerciasis in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin, has led to a decrease in both infection rates and progression to serious disease. Humans are the only host but measures are required over a long period because of the longevity of the worm (10–15 years).

Mansonellosis

Mansonella perstans is a filarial worm transmitted by biting midges of the genus *Culicoides*. Small numbers of microfilariae are found in the blood and although they do not cause serious disease there may be minor allergic reactions and an eosinophilia.

Dracunculiasis

Infection with the Guinea worm, *Dracunculus medinensis*, occurs when water fleas (copepods) containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature and the female worm, which can reach over 1 metre in length, migrates through connective and subcutaneous tissue for 9–18 months before surfacing

Taylor MJ, Hoerauf A, Bockarie M. Lymphatic filariasis and onchocerciasis. *Lancet* 2010; 376:1175–1185.

on the skin. The uterus of the worm ruptures, releasing larvae which are ingested by the small crustacean water fleas and the cycle is completed.

The *diagnosis* is clinical. The traditional *treatment*, extracting the worm over several days by winding it round a stick, is probably still the most effective. The worm should not be damaged. Antibiotics may be needed to control secondary infection.

Water fleas (and thus infective larvae) can be removed from drinking water by chemical treatment or by simple filtration. Large-scale eradication programmes have been in place for several years and the number of reported cases has fallen from over 3 million in 1985, to 4619 in 2008. The disease is now confined to small areas of Africa, mainly in Sudan and Ghana. Man is the only host of *D. medinensis* and it should therefore be possible to completely eradicate this parasite.

Human intestinal nematodes

Adult intestinal nematodes (also sometimes referred to as soil-transmitted helminths, or geohelminths) live in the human gut. There are two main types of life cycle, both including a soil-based stage. In some cases, infection is spread by ingestion of eggs (which often require a period of maturation in the environment), while in others, the eggs hatch in the soil and larvae penetrate directly through the skin of a new host. *Ascaris lumbricoides* larvae invade the duodenum and enter the venous system, via which they reach the lungs. They are eventually expectorated and swallowed, entering the intestine where they complete their maturation. *Strongyloides* is also unusual, in that it is the only nematode that is able to complete its life cycle in humans. Larvae may hatch before leaving the colon and so are able to reinfect the host by penetrating the intestinal wall and entering the venous system.

Ascariasis (roundworm infection)

Ascaris lumbricoides is a pale yellow worm, 20–35 cm in length (Fig. 4.35). It is found worldwide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae migrate through the tissues to the lungs before being expectorated and swallowed; adult worms are found in the small intestine. Ova are deposited in faeces and require a 2–4-month maturation in the soil before they are infective.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal

discomfort and anorexia. Worms can sometimes obstruct the small intestine, the most common site being at the ileocaecal valve. They may also occasionally invade the appendix, causing acute appendicitis, or the bile duct, resulting in biliary obstruction and suppurative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are rare in ascariasis, but the huge number of people infected means that on a global basis roundworm infection causes a significant burden of disease, especially in children.

Ascaris eggs can be identified in the stool and occasionally adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in Box 4.20. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

Threadworm (*Enterobius vermicularis*)

E. vermicularis is a small (2–12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine and adult worms are normally found in the colon. The gravid female deposits eggs around the anus causing intense itching, especially at night. Unlike *A. lumbricoides*, the eggs do not require a maturation period in soil and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen and are subsequently either ingested or inhaled. Apart from discomfort and local excoriation, infection is usually harmless.

Box 4.20 Drugs used for treating human intestinal nematodes (single dose unless otherwise stated)

		<i>Ascaris</i>	Hookworm	<i>Enterobius</i>	<i>Trichuris</i>	<i>Strongyloides</i>
Piperazine	75 mg/kg	++	+	++	–	–
Pyrantel pamoate	10 mg/kg	++	+	++	–	–
Oxantel pamoate	10 mg/kg	++	+	n/a	++	–
Albendazole	400 mg ^a	++	++	++	+	+
Mebendazole	500 mg ^b	++	++	++	+	+
Tiabendazole	25 mg/kg ^a	n/a	n/a	n/a	n/a	++
Levamisole	2.5 mg/kg	++	+	n/a	n/a	–
Ivermectin	200 µg/kg ^c	n/a	n/a	n/a	n/a	++

++, Highly effective; +, moderately effective; –, ineffective; n/a, drug not used for this indication/no data available.

^aTwice daily for 3 days in strongyloidiasis.

^bWHO recommended dose for developing countries; in UK commonly given as 100 mg single dose for threadworm or 100 mg twice daily for 3 days for whipworm.

^cOnce daily for 2 days.

Ova can be collected either using a moistened perianal swab, or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs are mebendazole and piperazine (Box 4.20). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

Whipworm (*Trichuris trichiura*)

Infections with whipworm are common worldwide, especially in poor communities with inadequate sanitation. Adult worms, which are 3–5 cm long, inhabit the terminal ileum and caecum, although in heavy infection they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces and require a maturation period of 3–4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy, or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in Box 4.20.

Hookworm infection

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus*, are found worldwide. They are relatively rare in developed countries, but very common in areas with poor sanitation and hygiene: overall about 25% of the world's population is affected. Hookworm infection is a major contributing factor to anaemia in the tropics. *A. duodenale* is found mainly in East Asia, North Africa and the Mediterranean, while *N. americanus* is the predominant species in South and Central America, South-east Asia and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm moist soil, producing infective filariform larvae. These penetrate directly through the skin of a new host and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and then swallowed, thus arriving at their definitive home.

Clinical features

Local irritation as the larvae penetrate the skin ('ground itch') may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnourishment, may cause iron deficiency anaemia and hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

Diagnosis and treatment

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia these will be present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication: albendazole given as a single dose is the best drug (Box 4.20). The WHO is promoting mass

treatment programmes for school-children in many parts of the world, together with treatment for schistosomiasis where appropriate.

Strongyloidiasis

Strongyloides stercoralis is a small (2 mm long) worm which lives in the small intestine. It is found in many parts of the tropics and subtropics and is especially common in Asia. Eggs hatch in the bowel and larvae are found in the stool. Usually these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel. Infective filariform larvae can therefore penetrate directly through the perianal skin, reinfecting the host. In this way, autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War have been found to have active strongyloidiasis over 50 years later. After skin penetration the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

Clinical features

S. stercoralis, following skin penetration, causes a similar local dermatitis to hookworm. In autoinfection this manifests as a migratory linear weal around the buttocks and lower abdomen (cutaneous larva currens). In heavy infections damage to the small intestinal mucosa can cause malabsorption, diarrhoea and even perforation. There is usually a persistent eosinophilia.

In patients who are immunosuppressed (e.g. by corticosteroid therapy or intercurrent illness) filariform larvae may penetrate directly through the bowel wall in huge numbers, causing an overwhelming and usually fatal generalized infection (the strongyloidiasis hyperinfestation syndrome). This condition is often complicated by a Gram-negative septicæmia due to bowel organisms.

Diagnosis and treatment

Motile larvae may be seen on stool microscopy, especially after a period of incubation. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 µg/kg daily for 2 days); albendazole (15 mg/kg 12-hourly for 3 days) is also effective.

Zoonotic nematodes

A number of nematodes which are principally parasites of animals may also affect man. The most common are described below.

Trichinosis

The normal hosts of *Trichinella spiralis*, the cause of trichinosis, include pigs, bears and warhogs. Man is infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae which penetrate the bowel wall and migrate through the tissues. Eventually, these larvae encyst in striated muscle.

Light infections are usually asymptomatic. Heavier loads of worms produce gastrointestinal symptoms as the adults establish themselves in the small intestine, followed by systemic symptoms as the larvae invade. The latter include fever, oedema and myalgia. Massive infection may occasionally be fatal, but usually the symptoms subside once the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia and serological tests. If necessary it can be confirmed by muscle biopsy a few weeks after infection. Albendazole (20 mg/kg for 7 days) given early in the course of the illness will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

Toxocariasis (visceral larva migrans)

Eggs of the dog roundworm, *Toxocara canis*, are occasionally ingested by humans, especially children. The eggs hatch and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but are then unable to complete their life cycle in a 'foreign' host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues including lungs, striated muscle, heart, brain and eye. In most cases, infection is asymptomatic and the larvae die without causing serious problems. In heavy infections, there may be generalized symptoms (fever and urticaria) and eosinophilia, as well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, while cardiac or neurological involvement is occasionally fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult and the diagnosis is usually made serologically. Albendazole 400 mg daily (5–10 mg/kg in children) for a week is the most effective treatment.

Cutaneous larva migrans (CLM)

CLM is caused by the larvae of the non-human hookworms *Ancylostoma braziliense* and *A. caninum*. Like human hookworms, these hatch in warm moist soil and then penetrate the skin. In man they are unable to complete a normal life cycle and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larva is accompanied by a clearly defined, serpiginous, itchy rash, which progresses at the rate of about 1 cm per day. There are usually no systemic symptoms. The diagnosis is purely clinical. Single larvae may be treated with a 15% solution of topical tiabendazole; multiple lesions require systemic therapy with a single dose of albendazole 400 mg or ivermectin 150–200 µg/kg.

Trematodes

Trematodes (flukes) are flat leaf-shaped worms. They have complex life cycles, often involving fresh water snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

Water-borne flukes

Schistosomiasis

Schistosomiasis affects over 200 million people in the tropics and subtropics, mostly in sub-Saharan Africa. Chronic infection causes significant morbidity and after malaria it has the most socioeconomic impact of any parasitic disease. Schistosomiasis is largely a disease of the rural poor, but has also been associated with major development projects such as dams and irrigation schemes.

Parasitology and pathogenesis

There are three species of schistosome which commonly cause disease in man: *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. *S. mekongi* and *S. intercalatum* also affect man but have very restricted distribution (Fig. 4.36). Eggs are passed in the urine or faeces of an infected person and hatch in fresh water to release the miracidia. These ciliated organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2–3 days. During this time, the cercariae can penetrate the skin or mucous membranes of the definitive host, man. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of *S. mansoni* and *S. japonicum* and the vesicular plexus for *S. haematobium*. Here, they may remain for many years, producing vast numbers of eggs. The majority of these are released in urine or faeces, but a small number become embedded in the bladder or bowel wall and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosome infection varies with species and stage of infection. In the early stages, there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited there may be a local inflammatory

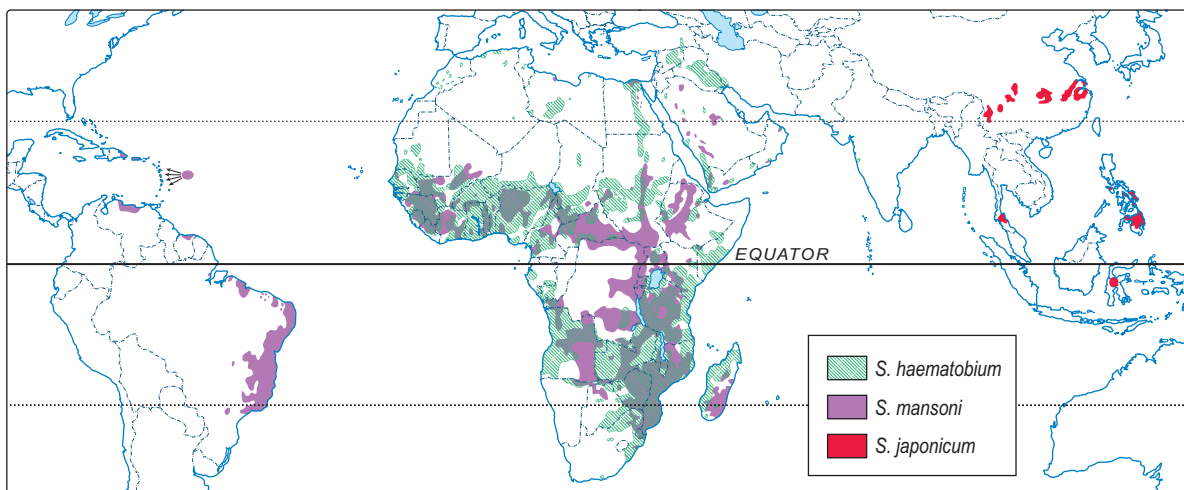

Figure 4.36 Schistosomiasis: geographical distribution.

response in the bowel or bladder, while ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in which large numbers of eggs accumulate in the tissues, leads to fibrosis, calcification and in some cases, dysplasia and malignant change. Morbidity and mortality are related to duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load, because of both increased exposure to infection and differences in the immune response between adults and children.

Clinical features

Cercarial penetration of the skin may cause local dermatitis ('swimmer's itch'). After a symptom-free period of 3–4 weeks, systemic allergic features may develop, including fever, rash, myalgia and pneumonitis (Katayama fever). These allergic phenomena are common in non-immune travellers, but are rarely seen in local populations, who are usually exposed to infection from early childhood onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2–3 months after infection.

S. haematobium infection (bilharzia). The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses there is increased urinary frequency and groin pain. Obstructive uropathy develops, leading to hydronephrosis, chronic kidney disease and recurrent urinary infection. There is a strong association between chronic urinary schistosomiasis and squamous cell bladder carcinoma. The genitalia may also be affected and ectopic eggs may cause pulmonary or neurological disease.

S. mansoni usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later the mucosal damage becomes more marked, with the formation of rectal polyps, deeper ulceration and eventually fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices and splenomegaly (see p. 345). Hepatocellular function is usually well preserved.

S. japonicum, unlike the other species, infects numerous other mammals apart from man. It is similar to *S. mansoni*, but infects both large and small bowel and produces a greater number of eggs. Disease therefore tends to be more severe and rapidly progressive. Hepatic involvement is more common and neurological involvement is seen in about 5% of cases.

Diagnosis

Schistosomiasis is suggested by relevant symptoms following fresh water exposure in an endemic area. In the early allergic stages, the diagnosis can only be made clinically. When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium* and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection, the best specimen for examination is a filtered mid-day urine sample. Parasites may also be found in semen and in rectal snip preparations. *S. mansoni* and *S. japonicum* eggs can usually be found in faeces or in a rectal snip. Serological tests are available and may be useful in the diagnosis of travellers returning from endemic areas, although the test may not become positive for 12 weeks after infection: a parasitological diagnosis should always be made if possible. In chronic disease, X-rays, ultrasound examinations and endoscopy may show abnormalities of the bowel or urinary tract, although these

Table 4.44 Treatment of trematode infections

^aMay be split to minimize nausea.
^bRepeated if necessary.
^cDepending on worm load.

are nonspecific. Liver biopsy may show the characteristic periportal fibrosis.

Management

The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely and reinfection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes and in light infections where there is no risk of re-exposure the drugs are usually curative. The most widely used is praziquantel (Table 4.44), which is effective against all species of schistosome, well-tolerated and reasonably cheap.

Prevention

Prevention of schistosomiasis is difficult and relies on a combination of approaches. Mass treatment of the population (especially children) will decrease the egg load in the community. Health education programmes, the provision of latrines and access to a safe water supply should decrease contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although manmade bodies of water can often be made less 'snail-friendly'. Travellers should be advised to avoid potentially infected water.

Food-borne flukes

Many flukes infect man via ingestion of an intermediate host, often fresh water fish.

Paragonimiasis

Over 20 million people are infected with lung flukes of the genus *Paragonimus*. The adult worms (of which the major species is *P. westermani*) live in the lungs, producing eggs which are expectorated or swallowed and passed in the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a fresh water snail. Larvae released from the snail seek out the second intermediate host, fresh water crustacea, in which they encyst as metacercariae. Humans and other mammalian hosts become infected after consuming uncooked shellfish. Cercariae penetrate the small intestinal wall and migrate directly from the peritoneum to the lungs across the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

FURTHER READING

Keiser J, Duthaler U, Utzinger J. Update on the diagnosis and treatment of food-borne trematode infections. *Curr Opin Infect Dis* 2010; 23:513–520.

King CH. Towards the elimination of schistosomiasis. *N Engl J Med* 2009; 360:106–109.

The common clinical features are fever, cough and mild haemoptysis. In heavy infections the disease may progress, sometimes mimicking pneumonia or pulmonary tuberculosis. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Radiological appearances are variable and nonspecific. Treatment is with praziquantel and prevention involves avoidance of inadequately cooked shellfish.

Liver flukes

The human liver flukes, *Clonorchis sinensis*, *Opisthorchis felineus* and *O. viverrini*, are almost entirely confined to East and South-east Asia, where they infect more than 20 million people. Adults live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a fresh water snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infection is often asymptomatic, but may be associated with cholangitis and biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with praziquantel and infection can be avoided by cooking fish adequately.

Other fluke infections

Man can also be infected with a variety of animal flukes, notably the liver fluke *Fasciola hepatica* and the intestinal fluke *Fasciolopsis buski*. Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation and then are consumed by animals or man. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver: during this stage it causes systemic allergic symptoms. After reaching the bile ducts, it causes similar problems to those of the other liver flukes. *F. buski* does not migrate after it excysts and causes mainly bowel symptoms.

Treatment

For treatment of trematode infections, see [Table 4.44](#).

Cestodes

Cestodes (tapeworms) are ribbon-shaped worms, which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which may either be released directly into the faeces, or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pig or cattle) and encyst in the tissues. Man ingests the cysts in undercooked meat and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary, but several adult tapeworms may co-exist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana*, which has no intermediate host and is transmitted from person to person by the faeco-oral route and *Taenia solium*, which produces cysticercosis (see below).

Taenia saginata

T. saginata, the beef tapeworm, may reach a length of several metres. It is common in all countries where undercooked

beef is eaten. The adult worm causes few if any symptoms. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg). It can be prevented by careful meat inspection, or by thorough cooking of beef.

Taenia solium and cysticercosis

T. solium, the pork tapeworm, is generally smaller than *T. saginata*, although it can still reach 6 metres in length. It is particularly common in South America, South Africa, China and parts of South-east Asia. As with *T. saginata*, infection is usually asymptomatic. The ova of the two species are identical, but the proglottids can be distinguished on inspection.

Pork tapeworm infection is acquired by eating uncooked pork. *Treatment* is with praziquantel or niclosamide. There is no evidence that drug treatment should be accompanied by a purgative, as was previously believed.

Cysticercosis is caused by ingestion of cysts rather than the adult worm and follows the ingestion of eggs from contaminated food and water. Faeco-oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis and patients with cysticercosis do not usually harbour tapeworms. Following the ingestion of eggs, the larvae are liberated, penetrate the intestinal wall and are carried to various parts of the body where they develop into cysticerci. These are cysts, 0.5–1 cm in diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle and brain.

Superficial cysts may be felt under the skin, but usually cause no significant symptoms. Cysts in the brain can cause a variety of problems including epilepsy, personality change, hydrocephalus and focal neurological signs (see p. 1130). These may only appear many years after infection.

Muscle cysts tend to calcify and are often visible on X-rays. Cutaneous cysts can be excised and examined. Brain cysts are less prone to calcification and are often only seen on CT or MRI scan. Serological tests may support the diagnosis.

Treatment of cysticercosis

The role of anthelmintics in cysticercosis remains controversial. Even in neurocysticercosis there is little evidence of benefit, although symptomatic patients with viable neurocysts should probably be treated. Albendazole 15 mg/kg daily for 8–20 days is the drug of choice; the alternative is praziquantel 50 mg/kg daily (in divided doses) for 15 days.

Successful treatment is accompanied by increased local inflammation and corticosteroids should be given during and after the course of anthelmintic. Prevention of cysticercosis depends on good hygiene, as well as on the eradication of human *T. solium* infection.

Cerebral cysticercosis

Anticonvulsants should be given for epilepsy and surgery may be indicated if there is hydrocephalus (see p. 1115).

Diphyllobothrium latum

Infection with the fish tapeworm, *D. latum*, is common in northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres, but like the other tapeworms usually causes no symptoms. A

Papular urticaria due to bedbug bites.

megaloblastic anaemia (due to competitive utilization of B₁₂ by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* species.

Hydatid disease

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus*. The adult worm lives in the gut of domestic and wild canines and the larval stages are usually found in sheep, cattle and camels. Man may become infected either from direct contact with dogs, or from food or water contaminated with dog faeces. After ingestion the parasites excyst, penetrate the small intestine wall and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Australia, Argentina, the Middle East and parts of East Africa.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%), followed by the lung (20%), kidneys (3%), brain (1%) and bone (1%). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity or biliary tree may occur. In the latter situation, intermittent jaundice, abdominal pain and fever associated with eosinophilia result. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases.

A related parasite of foxes, *E. multilocularis*, causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive and metastases may occur.

The diagnosis and treatment of hydatid liver disease are described on page 345.

ARTHROPOD ECTOPARASITES

Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

Local hypersensitivity reactions

Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular

urticaria, is nonspecific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods including mosquitoes, bugs, ticks, lice and mites. Occasionally, tick bites may cause a more severe systemic allergic response, especially in previously sensitized individuals.

Most of these parasites alight on man only to feed, but some species of lice live in very close proximity to the skin: body lice in clothing and head and pubic lice on human hairs (see Chapter 24).

Resident ectoparasite infections

Other ectoparasites are actually resident within the skin, causing more specific local lesions.

Scabies

See page 1202.

Jiggers

Jiggers is due to infection with the jigger flea, *Tunga penetrans*, and is common throughout South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, before the eggs are discharged onto the ground. The main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel and the area kept clean until it heals.

Myiasis

Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly, *Cordylobia anthropophaga* (found in sub-Saharan Africa), and the human botfly, *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions: a central breathing orifice may be visible. Again, the main risk is secondary infection. It is not always easy to extract the larva: covering it with petroleum jelly may bring it up in search of air.

Systemic envenoming

Many arthropods can cause local or systemic illness through envenoming, i.e. injection of venom.

The main role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in Table 4.4 and discussed in detail elsewhere.

SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain epidemic in all societies. The public health, social and economic consequences are extensive, both for acute infections and for their longer-term sequelae.

Those most likely to acquire STIs are young people, homo- and bisexual men and black and ethnic minority populations. Changes in incidence reflect high-risk sexual behaviour and inconsistent use of condoms. Increased travel both within and between countries, recreational drug use, alcohol and

more frequent partner change are also implicated. Multiple infections frequently co-exist, some of which may be asymptomatic and facilitate spread. Many people attend genitourinary medicine (GUM) clinics to seek information, advice and checks of their sexual health, but have no active STI.

Approach to the patient

Patients presenting with possible STIs are frequently anxious, embarrassed and concerned about confidentiality. Staff must

be alert to these issues and respond sensitively. The clinical setting must ensure privacy and reinforce confidentiality.

History

The history of the presenting complaint frequently focuses on genital symptoms, the three most common being vaginal discharge (Table 4.45), urethral discharge (Table 4.46) and genital ulceration (Table 4.47). Details should be obtained of any associated fever, pain, itch, malodour, genital swelling, skin rash, joint pains and eye symptoms. All patients should be asked about dysuria, haematuria and loin pain. A full general medical, family and drug history, particularly of any recent antibacterial or antiviral treatment, allergies and use of oral contraceptives, must be obtained. In women, menstrual, contraception and obstetric history should be obtained. Any past or current history of drug and/or alcohol misuse should be explored.

A detailed sexual history should be taken and include the number and types of sexual contacts (genital/genital, oral/genital, anal/genital, oral/anal) with dates, partner's sex, whether regular or casual partner, use of condoms and other forms of contraception, previous history of STIs including dates and treatment received, HIV testing and results and hepatitis B vaccination status.

Enquiries should be made concerning travel abroad to areas where antibiotic resistance is known or where particular pathogens are endemic.

Table 4.45 Causes of vaginal discharge

Infective	Non-infective
<i>Candida albicans</i>	Cervical polyps
<i>Trichomonas vaginalis</i>	Neoplasms
Bacterial vaginosis	Retained products (e.g. tampons)
<i>Neisseria gonorrhoeae</i>	Chemical irritation
<i>Chlamydia trachomatis</i>	
Herpes simplex virus	

Table 4.46 Causes of urethral discharge

Infective	Non-infective
<i>Neisseria gonorrhoeae</i>	Physical or chemical trauma

<i>Ureaplasma urealyticum</i>	
<i>Trichomonas vaginalis</i>	
Herpes simplex virus	
Human papillomavirus (meatal warts)	
Urinary tract infection (rare)	
<i>Treponema pallidum</i> (meatal chancre)	

Table 4.47 Causes of genital ulceration

Infective	Non-infective
Syphilis:	Behçet's syndrome
Primary chancre	Toxic epidermal necrolysis
Secondary mucous patches	Stevens-Johnson syndrome
Tertiary gumma	Carcinoma
Chancroid	Trauma
Lymphogranuloma venereum	
Donovanosis	
Herpes simplex:	
Primary	
Recurrent	
Herpes zoster	

Risk assessment of STI acquisition should be routinely undertaken. Those identified as being at high risk (e.g. frequent partner change, unprotected sex, use of drugs and/or alcohol to a level that reduces safer sex) should be offered risk reduction advice based on motivational interview techniques.

Examination

General examination must include the mouth, throat, skin and lymph nodes in all patients. Signs of HIV infection are covered on page 175. The inguinal, genital and perianal areas should be examined with a good light source. The groins should be palpated for lymphadenopathy and hernias. The pubic hair must be examined for nits and lice. The external genitalia must be examined for signs of erythema, fissures, ulcers, chancres, pigmented or hypopigmented areas and warts. Signs of trauma may be seen.

In men, the penile skin should be examined and the foreskin retracted to look for balanitis, ulceration, warts or tumours. The urethral meatus is located and the presence of discharge noted. Scrotal contents are palpated and the consistency of the testes and epididymis noted. A rectal examination/proctoscopy should be performed in patients with rectal symptoms, those who practise anoreceptive intercourse and patients with prostatic symptoms. A search for rectal warts is indicated in patients with perianal lesions.

In women, Bartholin's glands must be identified and examined. The cervix should be inspected for ulceration, discharge, bleeding and ectopy and the walls of the vagina for warts. A bimanual pelvic examination is performed to elicit adnexal tenderness or masses, cervical tenderness and to assess the position, size and mobility of the uterus. Rectal examination and proctoscopy are performed if the patient has symptoms or practises anoreceptive intercourse.

Investigations

Although the history and examination will guide investigation, it must be remembered that multiple infections may co-exist, some being asymptomatic. Full screening is indicated in any patient who may have been in contact with an STI.

Asymptomatic STI screening

A guide for the investigation of asymptomatic patients is given in Table 4.48.

- HIV antibody testing should be performed on an 'opt out' basis. If declined, the reasons why should be documented (see p. 178).
- Asymptomatic screening for hepatitis viruses in patients in groups at increased risk and who, if susceptible, should be offered vaccination.

Screening tests for hepatitis B. Tests should include hepatitis B surface antigen (HBsAg), which enables identification of currently infected individuals, and IgG anti-hepatitis B core, a marker of past infection and hence natural immunity. Screening is recommended for: men who have sex with men (MSM) and their sexual partners; sex workers; injecting drug users and their contacts; recipients of blood/blood products; needle-stick recipients; people who have been sexually assaulted; HIV-positive people; sexual partners of those who are HBsAg-positive and individuals from areas where hepatitis B is endemic.

Hepatitis A immunity screening and vaccination should be offered to MSM men in regions where an outbreak of hepatitis A has been reported, injecting drug users and patients with chronic hepatitis B or C, or other causes of chronic liver disease.

Table 4.48 Recommendations for screening and testing for sexually transmitted infections

	Swabs and urine investigations	Serological investigations
A: Asymptomatic patients		
Heterosexual men	Urine for Dual GC and <i>Chlamydia</i> NAAT or Urethral swabs for Dual GC and <i>Chlamydia</i> NAAT	Syphilis EIA HIV antibody Hepatitis B and C where indicated
Men who have sex with men (MSM)	Urine for Dual GC and <i>Chlamydia</i> NAAT or Urethral swabs for Dual GC and <i>Chlamydia</i> NAAT Rectal and throat swabs for dual GC and <i>Chlamydia</i> NAAT	
Women	Vulvovaginal swabs for Dual GC and <i>Chlamydia</i> NAAT or Urine for Dual GC and <i>Chlamydia</i> NAAT	Syphilis EIA HIV antibody Hepatitis B and C where indicated Pregnancy test if indicated
B: Symptomatic patients		
Men	Urethral swab for microscopic examination, <i>Chlamydia</i> and GC NAAT plus GC culture If swabs unobtainable then urine for Dual GC and <i>Chlamydia</i> NAAT If history or symptoms are indicative: Proctoscopy with rectal swabs for GC, <i>Chlamydia</i> LGV. Oropharyngeal swabs for dual GC and <i>Chlamydia</i> NAAT and/or culture. Urinary symptoms: urinalysis ± mid-stream urine sample	Syphilis EIA HIV antibody Hepatitis B and C where indicated
Women	<i>Cervical swabs</i> : Dual GC and <i>Chlamydia</i> NAAT microscopy and culture for GC <i>Urine</i> for Dual GC and <i>Chlamydia</i> NAAT if cervical/vaginal specimen has not been obtained <i>Vaginal swabs</i> : microscopy and culture for <i>Candida</i> , <i>Trichomonas</i> and bacterial vaginosis. NAATS for <i>Chlamydia</i> and GC if no other material <i>Rectal and oropharyngeal swabs</i> for GC and <i>Chlamydia</i> culture should be taken if indicated by the history or symptom pattern	
All patients with genital ulceration	Ulcerative conditions: Microscopic examination of material from the ulcer microscopy for evidence of early syphilis (dark ground microscopy), Donovanosis, chancroid or LGV Use of PCR techniques where available, for herpes, syphilis and LGV Culture for herpes simplex, <i>Haemophilus ducreyi</i>	Syphilis: EIA (IgM, IgG) and TPPA and cardiolipin tests for syphilis Herpes simplex virus: IgG by type-specific EIA, Immunoblot or Western blot Complement fixation tests for LGV
Other investigations depending on clinical circumstances	Cervical cytology; Pregnancy testing Stools for <i>Giardia</i> , <i>Shigella</i> or <i>Salmonella</i> from those practising oral/anal sex Smears and swabs from the subpreputial area in men with balanoposthitis (inflammation of glans penis and prepuce) for candidiasis Mid-stream urine for microscopy, culture and sensitivity	

GC, gonococcus; NAAT, nucleic acid amplification test; EIA, enzyme immunoassay; LGV lymphogranuloma venereum; TPPA, *Treponema pallidum* haemagglutination; TPPA, *Treponema pallidum* particle agglutination assay.

Adapted from UK national guidance, BASHH 2006: <http://www.bashh.org/documents/59/59.pdf>

Hepatitis C. Hepatitis C screening is recommended in injecting drug users, recipients of blood/blood products, needle-stick recipients, patients with HIV and the sexual partners of HCV-positive people, as treatment is frequently required.

Investigations for symptomatic patients

The investigations will depend on the clinical presentation. Common presentations include urethral discharge in men, vaginal discharge in women and genital ulceration. Recommended investigations are shown in Table 4.48.

Treatment, prevention and control

The treatment of specific conditions is considered in the appropriate section. Many GUM clinics keep basic stocks of medication and dispense directly to the patient. Treatment, particularly for those conditions that may be asymptomatic, is a major way to prevent onward transmission.

Tracing the sexual partners of patients is crucial in controlling the spread of STIs. The aims are to prevent the spread of infection within the community and to ensure that people with asymptomatic infection are properly treated. Appropriate antibiotic therapy may be offered to those who have had recent intercourse with someone known to have an active

infection (epidemiological treatment). Interviewing people about their sexual partners requires considerable tact and sensitivity and specialist health advisers are available in GUM clinics.

Over half of all STI diagnoses in the UK are in young adults (16–24 years). Prevention starts with education and information. People begin sexual activity at ever-younger ages and education programmes need to include school pupils as well as young adults. Education of health professionals is also crucial. Public health campaigns aimed at informing groups at particular risk are being implemented at a national level. The National *Chlamydia* Screening Programme in England (NCSP) aims to provide earlier detection and treatment for *Chlamydia* by providing easy access for under 25s to *Chlamydia* testing in community settings.

Avoiding multiple partners, correct and consistent use of condoms and avoiding sex with people who have symptoms of infection may reduce the risks of acquiring an STI. For those who change their sexual partners frequently, regular check-ups (approximately 3-monthly) are advisable. Once people develop symptoms they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

Sexual assault

The medical and psychological management of people who have been sexually assaulted requires particular sensitivity and should be undertaken by an experienced clinician in ways that reduce the risks of further trauma. Specialist sexual assault centres exist, providing multidisciplinary medical, forensic and psychological care in secure and sensitive settings. Post-traumatic stress disorder is common. Although most frequently reported by women, both women and men may suffer sexual assault. Investigations for and treatment of sexually transmitted infections in people who have been raped can be carried out in GUM departments. Collection of material for use as evidence, however, should be carried out within 7 days of the assault by a physician trained in forensic medicine and must take place before any other medical examinations are performed.

History

In addition to the general medical, gynaecological and contraceptive history, full details of the assault, including the exact sites of penetration, ejaculation by the assailant and condom use should be obtained, together with details of the sexual history both before and after the event.

Examination

Any injuries requiring immediate attention must be dealt with prior to any other examination or investigations. Accurate documentation of any trauma is necessary. Forced oral penetration may result in small palatal haemorrhages. In cases of forced anal penetration, anal examination including proctoscopy should be carried out, noting any trauma.

Investigations

The risk of STI acquisition from rape is variable and depends on the incidence of STI in the population. Ideally, a full STI screen at presentation, with appropriate specimens collected from all sites of actual or attempted penetration and a second examination 2 weeks later, is recommended. Nucleic acid amplification tests (NAATs) for *Neisseria gonorrhoeae* and for *Chlamydia trachomatis* can be carried out on urine specimens, avoiding the need for invasive examinations. A positive test should be confirmed by another method for medicolegal purposes. Gram-stained slides of urethral, cervical and rectal specimens for microscopy for gonococci should be performed. Bacterial vaginosis, yeasts and *Trichomonas vaginalis* (TV) tests should be carried out on vaginal material. Syphilis serology should be requested and a serum saved. Hepatitis B, HIV and hepatitis C testing should be offered. Specimens should be identified as having potential medicolegal implications.

Management

Preventative therapy for gonorrhoea and *Chlamydia* is advised using a single dose combination of ciprofloxacin 500 mg and azithromycin 1 g. An accelerated course of Hep B vaccine should be offered and may be of value up to 3 weeks after the event. HIV prophylaxis may be offered within 72 h of the assault, based upon risk assessment. Post-coital oral contraception may be given within 72 h of assault. Psychological care provision and appropriate referral to support agencies should be arranged. Sexual partners should be screened and treated if necessary. Follow-up at 2 weeks should be arranged to review the patient's needs and the prophylaxis regimens that are in place, with further follow-up as needed (e.g. to confirm or exclude acquisition of HBV, HIV or HCV infection). Following sexual assault, most people have a range of emotional and psychological

Figure 4.37 *Neisseria gonorrhoeae*: Gram-negative intracellular diplococci. (Courtesy of Dr B. Goh.)

reactions and will require varying levels of psychological support. Referral to a specialist centre is recommended.

CLINICAL SYNDROMES

HIV/AIDS

This is discussed in the section starting on [page 171](#).

Gonorrhoea (GC)

Neisseria gonorrhoeae (Gonococci, GC) is a Gram-negative intracellular diplococcus ([Fig. 4.37](#)), which infects epithelium particularly of the urogenital tract, rectum, pharynx and conjunctivae. Humans are the only host and the organism is spread by intimate physical contact. It is very intolerant to drying and although occasional reports of spread by fomites exist, this route of infection is extremely rare.

Clinical syndromes

Clinical features

Up to 50% of women and 10% of men are asymptomatic. The incubation period is 2–14 days with most symptoms occurring between days 2 and 5.

- **In men**, the most common syndrome is one of anterior urethritis causing dysuria and/or urethral discharge ([Fig. 4.38](#)). Complications include ascending infection involving the epididymis or prostate leading to acute or chronic infection. In MSM rectal infection may produce proctitis with pain, discharge and itch.
- **In women**, the primary site of infection is usually the endocervical canal. Symptoms include an increased or altered vaginal discharge, pelvic pain due to ascending infection, dysuria and intermenstrual bleeding. Complications include Bartholin's abscesses and in rare cases a perihepatitis (Fitzhugh–Curtis syndrome) can develop. On a global basis GC is one of the most common causes of female infertility. Rectal infection, due to local spread, occurs in women and is usually asymptomatic, as is pharyngeal infection. Conjunctival infection is seen in neonates born to infected mothers and is one cause of ophthalmia neonatorum.

Disseminated GC leads to arthritis (usually monoarticular or pauciarticular) (see [p. 533](#)) and characteristic papular or pustular rash with an erythematous base in association with fever and malaise. It is more common in women.

Clinical syndromes

Figure 4.38 *Neisseria gonorrhoeae*: purulent urethral discharge. (Courtesy of Dr B. Goh.)

Diagnosis

N. gonorrhoeae can be identified from infected areas by culture on selective media with a sensitivity of at least 95%. Nucleic acid amplification tests (NAATs) using urine specimens are non-invasive and highly sensitive, although they may give false-positive results. Microscopy of Gram-stained secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis. The sensitivity ranges from 90% in urethral specimens from symptomatic men to 50% in endocervical specimens. Microscopy should not be used for pharyngeal specimens. Blood culture and synovial fluid investigations should be performed in cases of disseminated GC. Co-existing pathogens such as *Chlamydia*, *Trichomonas* and syphilis must be sought.

Treatment is indicated in those patients who have a positive culture for GC, positive microscopy or a positive NAAT (this should be repeated because of false positives and all positives should be confirmed by cultures). Treatment is given to patients who have had recent sexual intercourse with someone with confirmed GC infection. Although *N. gonorrhoeae* is sensitive to a wide range of antimicrobial agents, antibiotic-resistant strains have shown a recent significant increase. Immediate therapy based on Gram-stained slides is usually initiated in the clinic, prior to culture and sensitivity results. Antibiotic choice is influenced by travel history or details known from contacts.

Single-dose ceftriaxone i.m. (500 mg) is recommended in the UK. Single-dose oral amoxicillin 3 g with probenecid 1 g, ciprofloxacin (500 mg) or ofloxacin (400 mg) may be used in areas with low prevalence of antibiotic resistance. (The CDC has reported high resistance, however, and recommends the addition of azithromycin 1 g orally.) Resistance to all antibiotics has recently been reported.

Longer courses of antibiotics are required for complicated infections. There should be at least one follow-up assessment and culture tests should be repeated at least 72 h after treatment is complete. All sexual contacts should be notified and then examined and treated as necessary.

Chlamydia trachomatis (CT)

This organism has a worldwide distribution. Genital infection with CT is common, with up to 14% of sexually active people

below the age of 25 years in the UK infected. It is regularly found in association with other pathogens: 20% of men and 40% of women with gonorrhoea have been found to have co-existing *Chlamydia* infections. In men 40% of non-gonococcal and post-gonococcal urethritis is due to *Chlamydia*. As CT is often asymptomatic much infection goes unrecognized and untreated, which sustains the infectious pool in the population. The long-term complications associated with *Chlamydia* infection, especially infertility, impose significant morbidity in the UK. The UK government has introduced a national *Chlamydia* screening programme in an attempt to decrease the rates of asymptomatic infection.

Clinical features

In men, CT gives rise to an anterior urethritis with dysuria and discharge; infection is asymptomatic in up to 50% and detected by contact tracing. Ascending infection leads to epididymitis. Rectal infection leading to proctitis occurs in men practising anoreceptive intercourse. *In women*, the most common site of infection is the endocervix, where it may go unnoticed; up to 80% of infection in women is asymptomatic. Symptoms include vaginal discharge, post-coital or intermenstrual bleeding and lower abdominal pain. Ascending infection causes acute salpingitis. Reactive arthritis (see p. 529) has been related to infection with *C. trachomatis*. Neonatal infection, acquired from the birth canal, can result in mucopurulent conjunctivitis and pneumonia.

Diagnosis

CT is an obligate intracellular bacterium, which complicates diagnosis. The nucleic acid amplification test (NAAT) is the diagnostic test of choice and is used as the 'standard of care' with a 90–95% sensitivity. Cell culture techniques provide the 'gold standard' and are 100% specific, but are expensive and require considerable expertise. Indirect diagnostic tests include direct fluorescent antibody (DIF) tests and enzyme immunoassays (EIA), but they are less reliable and none is diagnostic.

In men, first-voided urine samples are tested, or urethral swabs obtained. In women endocervical swabs are the best specimens and up to 20% additional positives will be detected if urethral swabs are also taken. Urine specimens are less reliable than endocervical swabs in women but are useful if a speculum examination is not possible.

Ligase chain reaction (LCR) can be used as an alternative to PCR.

Treatment

Tetracyclines or macrolide antibiotics are most commonly used to treat *Chlamydia*. Azithromycin 1 g as a single dose or doxycycline 100 mg 12-hourly for 7 days or are both effective for uncomplicated infection. Tetracyclines are contraindicated in pregnancy. Other effective regimens include erythromycin 500 mg four times daily. Routine test of cure is not necessary after treatment with doxycycline or azithromycin, although if symptoms persist or reinfection is suspected then further tests should be taken. NAATs may remain positive for up to 5 weeks after treatment as they pick up material from non-viable organisms. Sexual contacts must be traced, notified and treated, particularly as so many infections are clinically silent.

Urethritis

Urethritis is usually characterized in men by a discharge from the urethra, dysuria and varying degrees of discomfort within the penis. In 10–15% of cases there are no symptoms.

A wide array of aetiologies can give rise to the clinical picture and are divided into two broad bands: gonococcal or non-gonococcal urethritis (NGU). NGU occurring shortly after infection with gonorrhoea is known as postgonococcal urethritis (PGU). Gonococcal urethritis and *Chlamydia* urethritis (a major cause of NGU) are discussed above.

Trichomonas vaginalis, *Mycoplasma genitalium*, *Ureaplasma urealyticum* and *Bacteroides* spp. are responsible for a proportion of cases. HSV can cause urethritis in about 30% of cases of primary infection, considerably fewer in recurrent episodes. Other causes include syphilitic chancres and warts within the urethra. Non-sexually transmitted NGU may be due to urinary tract infections, prostatic infection, foreign bodies and strictures.

Clinical features

The urethral discharge is often mucoid and worse in the mornings. Crusting at the meatus or stains on underwear occur. Dysuria is common but not universal. Discomfort or itch within the penis may be present. The incubation period is 1–5 weeks with a mean of 2–3 weeks. Asymptomatic urethritis is a major reservoir of infection. *Reactive arthritis* (see p. 529) causing conjunctivitis with arthritis occurs, particularly in HLA B27-positive individuals.

Diagnosis

NAATs for gonorrhoea and *Chlamydia* should be performed in all men with symptoms of urethritis. In those who are negative, smears should be taken from the urethra when the patient has not voided urine for at least 4 h and should be Gram-stained and examined under a high-power ($\times 1000$) oil-immersion lens. The presence of five or more polymorphonuclear leucocytes per high-power field or a Gram-stained preparation from a centrifuged sample of a first passed urine specimen, containing >10 PMNL per high-power is diagnostic. Men who are symptomatic but have no objective evidence of urethritis should be re-examined and tested after holding urine overnight. Cultures for gonorrhoea must be taken together with specimens for *Chlamydia* testing.

Treatment

Therapy for NGU is with either azithromycin 1 g orally as a single dose or doxycycline 100 mg 12-hourly for 7 days. Sexual intercourse should be avoided. The vast majority of patients will show partial or total response. Sexual partners must be traced and treated; *C. trachomatis* can be isolated from the cervix in 50–60% of the female partners of men with PGU or NGU, many of whom are asymptomatic. This causes long-term morbidity in such women, acts as a reservoir of infection for the community and may lead to reinfection in the index case if not treated.

Recurrent/persistent NGU

This is a common and difficult clinical problem which is empirically defined as persistent or recurrent symptomatic urethritis occurring 30–90 days following treatment of acute NGU. It can occur in 20–60% of men treated for acute NGU. The usual time for patients to re-present is 2–3 weeks following treatment. Tests for organisms, e.g. *Mycoplasma*, *Chlamydia* and *Ureaplasma*, are usually negative. It is necessary to document objective evidence of urethritis, check adherence to treatment and establish any possible contact with untreated sexual partners. A further 1 week's treatment with erythromycin 500 mg four times a day for 2 weeks plus metronidazole 400 mg twice daily for 5 days may be given and any specific additional infection treated appropriately. If symptoms are mild and all partners have

been treated, patients should be reassured and further antibiotic therapy avoided. In cases of frequent recurrence and/or florid unresponsive urethritis, the prostate should be investigated and urethroscopy or cystoscopy performed to investigate possible strictures, periurethral fistulae or foreign bodies.

Lymphogranuloma venereum (LGV)

Chlamydia trachomatis types LGV 1, 2 and 3 (different biovars or variant prokaryotic strain) are responsible for this sexually transmitted infection. It is endemic in the tropics, with the highest incidences in Africa, India and South-east Asia. There has been a recent upsurge in UK-acquired LGV, particularly among HIV-infected men who have sex with men (MSM), presenting with rectal symptoms and associated genital ulceration. Many have also been hepatitis C co-infected. The L2 serovar (different antigenic properties) has been the predominant strain. The Health Protection Agency has enhanced LGV surveillance to track the current UK outbreak.

Clinical features

There are three characteristic stages. The primary lesion is a painless ulcerating papule on the genitalia occurring 7–21 days following exposure. It is frequently unnoticed. A few days to weeks after this heals, regional lymphadenopathy develops. The lymph nodes are painful and fixed and the overlying skin develops a dusky erythematous appearance. Finally, nodes may become fluctuant (buboes) and can rupture. Acute LGV also presents as proctitis with perirectal abscesses, the appearances sometimes resembling anorectal Crohn's disease. The destruction of local lymph nodes can lead to lymphoedema of the genitalia.

Diagnosis

The diagnosis is often made on the basis of the characteristic clinical picture after other causes of genital ulceration or inguinal lymphadenopathy have been excluded. Syphilis and genital herpes must be excluded. The laboratory investigations have become more sensitive and specific:

- Detection of nucleic acid (DNA). Nucleic acid amplification tests for LGV serovar are now available. Positive samples should be confirmed by real-time PCR for LGV-specific DNA.
- Isolation of *C. trachomatis* from clinical lesions in tissue culture remains the most specific test; however, sensitivity is only 75–85%.
- *Chlamydia trachomatis* serology. Complement fixation (CF) tests, single L-type immunofluorescence test and micro-immunofluorescence test (micro-IF) (the latter being the most accurate). A four-fold rise in antibody titre in the course of the illness or a single point titre of $>1/64$ is considered to be diagnostic.

Treatment

Early treatment is critical to prevent the chronic phase. Doxycycline (100 mg twice daily for 21 days) or erythromycin (500 mg four times daily for 21 days) is efficacious. Follow-up should continue until signs and symptoms have resolved, usually 3–6 weeks. Chronic infection may result in extensive scarring and abscess and sinus formation. Surgical drainage or reconstructive surgery is sometimes required. HIV and hepatitis C screening should be recommended. Sexual partners in the 30 days prior to onset should be notified, examined and treated if necessary.

Table 4.49 Classification and clinical features of syphilis

Clinical features	
Acquired	
Early stages	
Primary	Hard chancre Painless, regional lymphadenopathy
Secondary	<i>General:</i> Fever, malaise, arthralgia, sore throat and generalized lymphadenopathy <i>Skin:</i> Red/brown maculopapular non-itchy, sometimes scaly rash; condylomata lata <i>Mucous membranes:</i> Mucous patches, 'snail-track' ulcers in oropharynx and on genitalia
Late stages	
Tertiary	<i>Late benign:</i> Gummas (bone and viscera) <i>Cardiovascular:</i> Aortitis and aortic regurgitation <i>Neurosyphilis:</i> Meningovascular involvement, general paralysis of the insane (GPI) and tabes dorsalis
Congenital	
Early stages	Stillbirth or failure to thrive 'Snuffles' (nasal infection with discharge) Skin and mucous membrane lesions as in secondary syphilis
Late stages	'Stigmata': Hutchinson's teeth, 'sabre' tibia and abnormalities of long bones, keratitis, uveitis, facial gummas and CNS disease

Syphilis

Syphilis is a chronic systemic disease, which is acquired or congenital. In its early stages diagnosis and treatment are straightforward but untreated it can cause complex sequelae in many organs and eventually lead to death. There has been a marked increase in the incidence of syphilis over the past decade. A majority of these infections occur in MSM, many of whom are co-infected with HIV.

The causative organism, *Treponema pallidum* (TP), is a motile spirochaete that is acquired either by close sexual contact or can be transmitted transplacentally. The organism enters the new host through breaches in squamous or columnar epithelium. Primary infection of non-genital sites may occasionally occur but is rare.

Both acquired and congenital syphilis have early and late stages, each of which has classic clinical features (Table 4.49).

- **Primary.** Between 10 and 90 days (mean 21 days) after exposure to the pathogen a papule develops at the site of inoculation. This ulcerates to become a painless, firm chancre. There is usually painless regional lymphadenopathy in association. The primary lesion may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 2–3 weeks.
- **Secondary.** Between 4 and 10 weeks after the appearance of the primary lesion constitutional symptoms with fever, sore throat, malaise and arthralgia appear. Any organ may be affected – leading, for example, to hepatitis, nephritis, arthritis and meningitis. In a minority of cases the primary chancre may still be present and should be sought.

Signs include:

- Generalized lymphadenopathy (50%)
- Generalized skin rashes involving the whole body including the palms and soles but excluding the face

Figure 4.39 Rash of secondary syphilis on the palms. (Courtesy of Dr B. Goh.)

(75%) – the rash, which rarely itches, may take many different forms, ranging from pink macules, through coppery papules, to frank pustules (Fig. 4.39)

- Condylomata lata: warty, plaque-like lesions found in the perianal area and other moist body sites
- Superficial confluent ulceration of mucosal surfaces – found in the mouth and on the genitalia, described as 'snail track ulcers'
- Acute neurological signs in less than 10% of cases (e.g. aseptic meningitis).

Untreated early syphilis in pregnant women leads to fetal infection in at least 70% of cases and may result in stillbirth in up to 30%.

- **Latent.** Without treatment, symptoms and signs abate over 3–12 weeks, but in up to 20% of individuals, may recur during a period known as early latency, a 2-year period in the UK (1 year in USA). Late latency is based on reactive syphilis serology with no clinical manifestations for at least 2 years. This can continue for many years before the late stages of syphilis become apparent.
- **Tertiary.** Late benign syphilis, so called because of its response to therapy rather than its clinical manifestations, generally involves the skin and the bones. The characteristic lesion, the gumma (granulomatous, sometimes ulcerating, lesions), can occur anywhere in the skin, frequently at sites of trauma. Gummas are commonly found in the skull, tibia, fibula and clavicle, although any bone may be involved. Visceral gummas occur mainly in the liver (hepar lobatum) and the testes.

Cardiovascular and neurosyphilis are discussed on pages 669, 1129.

Congenital syphilis

Congenital syphilis usually becomes apparent between the 2nd and 6th week after birth, early signs being nasal discharge, skin and mucous membrane lesions and failure to thrive. Signs of late syphilis generally do not appear until after 2 years of age and take the form of 'stigmata' relating to early damage to developing structures, particularly teeth and long bones. Other late manifestations parallel those of adult tertiary syphilis.

Investigations for diagnosis

Treponema pallidum is not amenable to *in vitro* culture – the most sensitive and specific method is identification by dark-ground microscopy. Organisms may be found in variable

Table 4.50 Syphilis serology

Stage of infection	Results			
	EIA	FTA-abs	TPHA/TPPA	VDRL/RPR
Very early primary	–	–	–	–
Early primary	+ (IgM)	+	–	–

Biological false positive	–	–	–	+

EIA, enzyme immunoassay; FTA-abs, fluorescent *Treponema* antibodies absorbed; TPHA/TPPA, *Treponema pallidum* haemagglutination/particle agglutination assay; VDRL, Venereal Disease Research Laboratory; RPR, rapid plasma reagin.

numbers, from primary chancres and the mucous patches of secondary lesions. Individuals with either primary or secondary disease are highly infectious.

Serological tests used in diagnosis are either treponemal-specific or nonspecific (cardiolipin test) (Table 4.50):

- **Treponemal specific.** The *T. pallidum* enzyme immunoassay (EIA). *T. pallidum* haemagglutination or particle agglutination assay (TPHA/TPPA) and fluorescent treponemal antibodies absorbed (FTA-abs) test are both highly specific for treponemal disease but will not differentiate between syphilis and other treponemal infection such as yaws. These tests usually remain positive for life, even after treatment.
- **Treponemal nonspecific.** The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests are nonspecific, becoming positive within 3–4 weeks of the primary infection. They are quantifiable tests which can be used to monitor treatment efficacy and are helpful in assessing disease activity. They generally become negative by 6 months after treatment in early syphilis. The VDRL may also become negative in untreated patients (50% of patients with late-stage syphilis) or remain positive after treatment in late stage. False-positive results may occur in other conditions – particularly infectious mononucleosis, hepatitis, *Mycoplasma* infections, some protozoal infections, cirrhosis, malignancy, autoimmune disease and chronic infections.

The EIA is the screening test of choice and can detect both IgM and IgG antibodies. A positive test is then confirmed with the TPHA/TPPA and VDRL/RPR tests. All serological investigations may be negative in early primary syphilis; the EIA IgM and the FTA-abs being the earliest tests to be positive. The diagnosis will then hinge on positive dark-ground microscopy. Treatment should not be delayed if serological tests are negative in such situations.

Examination of the CSF for evidence of neurosyphilis is indicated in those patients with syphilis who demonstrate neurological signs and symptoms, have a high titre of non-treponemal tests (usually taken to be >1:32), those who have any evidence of treatment failure and HIV co-infected patients with late latent syphilis or syphilis of unknown duration. A chest X-ray should also be performed.

Treatment

Treponemocidal levels of antibiotic must be maintained in serum for at least 7 days in early syphilis to cover the slow division time of the organism (30 h). In late syphilis treponemes may divide even more slowly requiring longer therapy.

- **Early syphilis** (primary or secondary) should be treated with long-acting penicillin such as procaine benzylpenicillin (procaine penicillin) (e.g. Jenacillin A, which also contains benzylpenicillin) 600 mg intramuscularly daily for 10 days.
- **For late-stage syphilis**, particularly when there is cardiovascular or neurological involvement, the treatment course should be extended for a further week.

For patients sensitive to penicillin, either doxycycline 200 mg daily or erythromycin 500 mg four times daily is given orally for 2–4 weeks depending on the stage of the infection. Non-compliant patients can be treated with a single dose of benzathine penicillin G 2.4 g intramuscularly. Azithromycin is not recommended following evidence of resistance. The diagnosis and management of syphilis in HIV co-infected patients remains unaltered; however, if untreated it may advance more rapidly than in HIV-negative patients and have a higher incidence of neurosyphilis. The *Jarisch–Herxheimer reaction*, which is due to release of TNF- α , IL-6 and IL-8, is seen in 50% of patients with primary syphilis and up to 90% of patients with secondary syphilis. It occurs about 8 h after the first injection and usually consists of mild fever, malaise and headache lasting several hours. In cardiovascular or neurosyphilis the reaction, although rare, may be severe and exacerbate the clinical manifestations. Prednisolone given for 24 h prior to therapy may ameliorate the reaction but there is little evidence to support its use. Penicillin should not be withheld because of the Jarisch–Herxheimer reaction; since it is not a dose-related phenomenon, there is no value in giving a smaller dose.

The *prognosis* depends on the stage at which the infection is treated. Early and early latent syphilis have an excellent outlook but once extensive tissue damage has occurred in the later stages the damage will not be reversed although the process may be halted. Symptoms in cardiovascular disease and neurosyphilis may therefore persist.

All patients treated for early syphilis must be followed up at regular intervals for the first year following treatment. Serological markers with a fall in titre of the VDRL/RPR of at least four-fold is consistent with adequate treatment for early syphilis. The sexual partners of all patients with syphilis and the parents and siblings of patients with congenital syphilis must be contacted and screened. Babies born to mothers who have been treated for syphilis in pregnancy are retreated at birth.

Chancroid

Chancroid or soft chancre is an acute STI caused by *Haemophilus ducreyi*. Although a less common cause of genital

ulceration than HSV-2, it is prevalent in parts of Africa and Asia. It is rare in the UK with cases usually associated with travel to or partners from endemic areas. Epidemiological studies in Africa have shown an association between genital ulcer disease, frequently chancroid and the acquisition of HIV infection. A new urgency to control chancroid has resulted from these observations.

Clinical features

The incubation period is 3–10 days. At the site of inoculation an erythematous papular lesion forms which then breaks down into an ulcer. The ulcer frequently has a necrotic base, a ragged edge, bleeds easily and is painful. Several ulcers may merge to form giant serpiginous lesions. Ulcers appear most commonly on the prepuce and frenulum in men and can erode through tissues. In women the most commonly affected site is the vaginal entrance and the perineum and lesions sometimes go unnoticed.

At the same time, inguinal lymphadenopathy develops (usually unilateral) and can progress to form large buboes which suppurate.

Diagnosis and treatment

Chancroid must be differentiated from other genital ulcer diseases (see Table 4.47). Co-infection with syphilis and herpes simplex is common. Isolation of *H. ducreyi*, a fastidious organism, in specialized culture media is definitive but difficult. Swabs should be taken from the ulcer and material aspirated from the local lymph nodes for culture. Polymerase chain reaction (PCR) techniques are available. Gram stains of clinical material may show characteristic coccobacilli, but this is an insensitive test. Detection of antibody to *H. ducreyi* using EIA may be useful for population surveillance but, at an individual level, lacks sensitivity and specificity. A 'probable diagnosis' may be made if the patient has the appropriate clinical picture, without evidence of *T. pallidum* or herpes simplex infection.

Single-dose regimens include azithromycin 1 g orally or ceftriaxone 250 mg i.m. Other regimens include ciprofloxacin 500 mg twice daily for 3 days, erythromycin 500 mg four times daily for 7 days. Clinically significant plasmid-mediated antibiotic resistance in *H. ducreyi* is developing.

Patients should be followed up at 3–7 days, when the ulcers should be responding if the treatment is successful.

Sexual partners should be notified, examined and treated epidemiologically, as asymptomatic carriage has been reported.

HIV-infected patients should be closely monitored, as healing may be slower. Multiple-dose regimens are needed in HIV patients since treatment failures have been reported with single-dose therapy.

Donovanosis

Donovanosis is the least common of all STIs in North America and Europe, but is endemic in the tropics and subtropics, particularly the Caribbean, South-east Asia and South India. Infection is caused by *Klebsiella granulomatis*, a short, encapsulated Gram-negative bacillus. The infection was also known as granuloma inguinale. Although sexual contact appears to be the most usual mode of transmission, the infection rates are low, even between sexual partners of many years' standing.

Clinical features

In the vast majority of patients, the characteristic, heaped-up ulcerating lesion with prolific red granulation tissue appears

on the external genitalia, perianal skin or the inguinal region within 1–4 weeks of exposure. It is rarely painful. Almost any cutaneous or mucous membrane site can be involved, including the mouth and anorectal regions. Extension of the primary infection from the external genitalia to the inguinal regions produces the characteristic lesion, the 'pseudo-bubo'.

Diagnosis and treatment

The clinical appearance usually strongly suggests the diagnosis but *K. granulomatis* (Donovan bodies) can be identified intracellularly in scrapings or biopsies of an ulcer. Successful culture has only recently been reported and PCR techniques and serological methods of diagnosis are being developed, but none is routinely available.

Antibiotic treatment should be given until the lesions have healed. A minimum of 3 weeks' treatment is recommended. Regimens include doxycycline 100 mg twice daily, co-trimoxazole 960 mg twice daily, azithromycin 500 mg daily or 1 g weekly, or ceftriaxone 1 g daily.

Sexual partners should be notified, examined and treated if necessary.

Herpes simplex (also see p. 1199)

Genital herpes is one of the most common STIs worldwide and the most common ulcerative STI in the UK. The peak incidence is in 16- to 24-year-olds of both sexes, with women having higher rates of diagnosis than men. Infection, which is lifelong, may be either primary or recurrent. Transmission occurs during close contact with a person who is shedding virus (who may well be asymptomatic). Historically, most genital herpes is due to HSV type 2. However, genital contact with oral lesions caused by HSV-1 can also produce genital infection and rates of HSV-1-associated genital herpes are approaching 50% in some parts of the world.

Susceptible mucous membranes include the genital tract, rectum, mouth and oropharynx. The virus has the ability to establish latency in the dorsal root ganglia by ascending peripheral sensory nerves from the area of inoculation. It is this ability which allows for recurrent attacks.

Clinical features

Primary genital herpes is usually accompanied by systemic symptoms of varying severity including fever, myalgia and headache. Multiple painful shallow ulcers develop, which may coalesce (Fig. 4.40). Atypical lesions are common. Tender inguinal lymphadenopathy is usual. Over a period of 10–14 days the lesions develop crusts and dry. In women with vulval lesions the cervix is almost always involved.

Figure 4.40 Herpes simplex rash on the penis. (Courtesy of Dr B. Goh.)

Rectal infection may lead to a florid proctitis. Neurological complications can include aseptic meningitis and/or involvement of the sacral autonomic plexus leading to retention of urine. Asymptomatic primary infection has been reported but is rare. Serological surveys indicate that only about 10% of individuals with antibodies to HSV-2 give a clinical history of genital lesions, indicating that asymptomatic primary infection is the norm.

Recurrent attacks occur in a significant proportion of people following the initial episode and are more likely with HSV type 2 infections. Precipitating factors vary, as does the frequency of recurrence. A symptom prodrome is present in some people prior to the appearance of lesions. Systemic symptoms are rare in recurrent attacks.

The clinical manifestations in immunosuppressed patients (including those with HIV) may be more severe, asymptomatic shedding increased and recurrences occurring with greater frequency. Systemic spread has been documented (see p. 191).

Diagnosis

The history and examination can be highly suggestive of HSV infection.

- A firm diagnosis can routinely be made only on the basis of detection of virus from within lesions.
- Swabs should be taken from the base of lesions and placed in viral transport medium. Virus is most easily isolated from new lesions.
- HSV DNA detection by polymerase chain reaction (PCR) has increased the rates of detection compared with virus culture.
- Real-time PCR assays are highly specific although not available in all laboratories.

Type-specific immune responses can be found 8–12 weeks following primary infection and indicate HSV infection at some time. False negatives may be found early after infection. IgM assays are unreliable.

Management

- **Primary.** Saltwater bathing or sitting in a warm bath is soothing and may allow the patient to pass urine with some degree of comfort. Aciclovir 200 mg five times daily, famciclovir 250 mg three times daily or valaciclovir 500 mg twice daily, all for 5 days, are useful if patients are seen while new lesions are still forming. If lesions are already crusting, antiviral therapy will do little to change the clinical course. Secondary bacterial infection occasionally occurs and should be treated. Rest, analgesia and antipyretics should be advised.
- **Recurrence.** Recurrent attacks tend to be less severe and can be managed with simple measures such as saltwater bathing. Psychological morbidity is associated with recurrent genital herpes and frequent recurrences impose strains on relationships; patients need considerable support. Long-term suppressive therapy is given in patients with frequent recurrences. An initial course of aciclovir 400 mg twice daily or valaciclovir 250 mg twice daily for 6–12 months significantly reduces the frequency of attacks, although there may still be some breakthrough. Therapy should be discontinued after 12 months and the frequency of recurrent attacks reassessed.

HSV in pregnancy

The potential risk of infection to the neonate needs to be considered in addition to the health of the mother.

Infection occurs either transplacentally (very rare) or via the birth canal. If HSV is acquired for the first time during pregnancy, transplacental infection of the fetus may, rarely, occur. Management of primary HSV in the 1st or 2nd trimester will depend on the woman's clinical condition and aciclovir can be prescribed in standard doses. Aciclovir, given at a dose of 400 mg three times a day to accommodate altered pharmacokinetics of the drug in late pregnancy, during the last 4 weeks of pregnancy, may prevent recurrence at term.

Symptomatic primary acquisition in the 3rd trimester or at term with high levels of viral shedding usually leads to delivery by caesarean section.

For women with previous infection, the risk for the baby acquiring HSV from the birth canal is very low in recurrent attacks. Only those with genital lesions at the onset of labour are delivered by caesarean section. Sequential cultures during the last weeks of pregnancy to predict viral shedding at term are no longer indicated.

Prevention and control

Patients must be advised that they are infectious when lesions are present; sexual intercourse should be avoided during this time or during prodromal stages. Condoms may not be effective as lesions may occur outside the areas covered. Sexual partners should be notified, examined and given information on avoiding infection. Asymptomatic viral shedding is a cause of onward transmission. It is most common in HSV-2, during the first 12 months following infection and in those with frequent symptomatic HSV. Antiviral drugs reduce shedding and onward transmission.

Human papillomavirus (HPV) warts

Anogenital warts are among the most common sexually acquired infections. The causative agent is human papillomavirus (HPV), especially types 6 and 11 with types 16 and 18 causing a majority of cases of cervical carcinoma (see p. 100). HPV is acquired by direct sexual contact with a person with either clinical or subclinical infection. Genital HPV infection is common, with only a small proportion of those infected being symptomatic. Neonates may acquire HPV from an infected birth canal, which may result either in anogenital warts or in laryngeal papillomas. The incubation period ranges from 2 weeks to 8 months or even longer.

Clinical features

Warts develop around the external genitalia in women, usually starting at the fourchette, and involve the perianal region. The vagina may be infected. Flat warts may develop on the cervix and are not easily visible on routine examination. Such lesions are associated with cervical intraepithelial neoplasia. In men, the penile shaft and subpreputial space are the most common sites, although warts involve the urethra and meatus. Perianal lesions are more common in men who practise anoreceptive intercourse but they can be found in any patient. The rectum may become involved. Warts become more florid during pregnancy or in immunosuppressed patients.

Diagnosis

The diagnosis is essentially clinical. It is critical to differentiate condylomata lata of secondary syphilis. Unusual lesions should be biopsied if the diagnosis is in doubt. Up to 30% of patients have co-existing infections with other STIs and a full screen must be performed.

FURTHER READING

Giuliano AR, Lee J-H, Fulp W et al. Incidence and clearance of genital human papillomavirus infection in men (HIM): a cohort study. *Lancet* 2011; 377:932–940.

Treatment

Significant failure and relapse rates are seen with current treatment modalities. Choice of treatment will depend on the number and distribution of lesions. Local agents, including podophyllin extract (15–25% solution, once or twice weekly), podophyllotoxin (0.5% solution or 1.5% cream in cycles) and trichloroacetic acid, are useful for non-keratinized lesions. Those that are keratinized respond better to physical therapy, e.g. cryotherapy, electrocautery or laser ablation. Imiquimod, an immune response modifier, induces a cytokine response when applied to skin infected with HPV (5% cream used three times a week) and is indicated in both types of lesion. Podophyllin, podophyllotoxin and imiquimod are not advised in pregnancy. Patients co-infected with HIV may have a poorer response to treatment and higher rates of intraepithelial neoplasia. Sexual contacts should be examined and treated if necessary. In view of the difficulties of diagnosing subclinical HPV, condoms should be used for up to 8 months after treatment. Because of the association of HPV with cervical intraepithelial neoplasia, women with warts and female partners of men with warts are advised to have regular cervical screening, i.e. every 3 years. Colposcopy may be useful in women with vaginal and cervical warts.

Prevention/vaccination

Two vaccines exist against HPV. One is effective against HPV types 16 and 18 and the second against types 6, 11, 16 and 18. Both vaccines, based on a DNA-free HPV capsid, are strongly immunogenic and act by inducing a neutralizing antibody response and enhancing CD4 memory cell function. They are given over 6 months in three divided doses, with an excellent safety profile. Up to 98% serological responses, maintained for over 4 years, have been reported from early trials. In placebo-controlled clinical trials of the quadrivalent vaccine a highly significant reduction in low- and high-grade cervical dysplasia, vulval pre-cancers and external genital warts has been demonstrated. Vaccination is most beneficial in those who have not yet been exposed to HPV infection, with a recommendation that it be given before people become sexually active. Although initially considered to be most useful for women and girls, vaccination of boys to prevent both genital warts and the transmission of oncogenic HPV strains is under consideration. Routine HPV vaccination commenced in the UK in late 2008, initially for girls of about 12 years of age, with a second catch-up opportunity at about 18 years of age.

Hepatitis B

This is discussed in [Chapter 7](#). Sexual contacts should be screened and given vaccine if they are not immune (see p. 318).

Trichomoniasis

Trichomonas vaginalis (TV) is a flagellated protozoon which is predominantly sexually transmitted. It is able to attach to squamous epithelium and can infect the vagina and urethra. *Trichomonas* may be acquired perinatally in babies born to infected mothers.

Infected women may, unusually, be asymptomatic. Commonly the major complaints are of vaginal discharge, which is offensive and of local irritation. Men usually present as the asymptomatic sexual partners of infected women, although they may complain of urethral discharge, irritation or urinary frequency.

Examination often reveals a frothy yellowish vaginal discharge and erythematous vaginal walls. The cervix may have multiple small haemorrhagic areas which lead to the description 'strawberry cervix'. *Trichomonas* infection in pregnancy has been associated with pre-term delivery and low birth weight.

Diagnosis and treatment

Phase-contrast, dark-ground microscopy of a drop of vaginal discharge shows TV swimming with a characteristic motion in 40–80% of female patients. Similar preparations from the male urethra will only be positive in about 30% of cases. Many polymorphonuclear leucocytes are also seen. Culture techniques are good and confirm the diagnosis. *Trichomonas* is sometimes observed on cervical cytology with 60–80% accuracy in diagnosis. New, highly sensitive and specific tests based on polymerase chain reactions are being developed.

Metronidazole is the treatment of choice, either 2 g orally as a single dose or 400 mg twice daily for 7 days. There is some evidence of metronidazole resistance and tinidazole may be effective in these cases. Topical therapy with intravaginal tinidazole can be effective, but if extravaginal infection exists this may not be eradicated and vaginal infection reoccurs. Male partners should be treated, especially as they are likely to be asymptomatic and more difficult to detect.

Candidiasis

Vulvovaginal infection with *Candida albicans* is extremely common. The organism is also responsible for balanitis in men. *Candida* can be isolated from the vagina in a high proportion of women of childbearing age, many of whom will have no symptoms.

The role of *Candida* as pathogen or commensal is difficult to disentangle and it may be changes in host environment which allow the organism to produce pathological effects. Predisposing factors include pregnancy, diabetes and the use of broad-spectrum antibiotics and corticosteroids. Immunosuppression can result in more florid infection.

Clinical features

In women, pruritus vulvae is the dominant symptom. Vaginal discharge is present in varying degrees. Many women have only one or occasional isolated episodes. Recurrent candidiasis (four or more symptomatic episodes annually) occurs in up to 5% of healthy women of reproductive age. Examination reveals erythema and swelling of the vulva with broken skin in severe cases. The vagina may contain adherent curdy discharge. Men may have a florid balanoposthitis. More commonly, self-limiting burning penile irritation immediately after sexual intercourse with an infected partner is described. Diabetes must be excluded in men with balanoposthitis.

Diagnosis

Microscopic examination of a smear from the vaginal wall reveals the presence of spores and mycelia. Culture of swabs should be undertaken but may be positive in women with no symptoms. *Trichomonas* and bacterial vaginosis must be considered in women with itch and discharge.

Treatment

Topical. Pessaries or creams containing one of the imidazole antifungals such as clotrimazole 500 mg single

dose used intravaginally are usually effective. Nystatin is also useful.

Oral. The triazole drugs such as fluconazole 150 mg as a single dose or itraconazole 200 mg twice in 1 day are used systemically where topical therapy has failed or is inappropriate. Recurrent candidiasis may be treated with fluconazole 100 mg weekly for 6 months or clotrimazole pessary, 500 mg weekly for 6 months.

The evidence for sexual transmission of *Candida* is slight and there is no evidence that treatment of male partners reduces recurrences in women.

Bacterial vaginosis

Bacterial vaginosis (BV) is a disorder characterized by an offensive vaginal discharge. The aetiology and pathogenesis are unclear but a mixed flora of *Gardnerella vaginalis*, anaerobes including *Bacteroides*, *Mobiluncus* spp. and *Mycoplasma hominis* replaces the normal lactobacilli of the vagina. Amines and their breakdown products from the abnormal vaginal flora are thought to be responsible for the characteristic odour associated with the condition. As vaginal inflammation is not part of the syndrome, the term vaginosis is used rather than vaginitis. The condition has been shown to be more common in black women than in white. It is not regarded as a sexually transmitted disease.

Clinical features

Vaginal discharge and odour are the commonest complaints, although a proportion of women are asymptomatic. A homogeneous, greyish white, adherent discharge is present in the vagina, the pH of which is raised (>5). Associated complications are ill-defined but may include chorioamnionitis and an increased incidence of premature labour in pregnant women. Whether BV predisposes non-pregnant women to upper genital tract infection is unclear.

Diagnosis

Different authors have differing criteria for making the diagnosis of BV. In general, it is accepted that three of the following should be present for the diagnosis to be made:

- Characteristic vaginal discharge
- The amine test: raised vaginal pH using narrow-range indicator paper (>4.7)
- A fishy odour on mixing a drop of discharge with 10% potassium hydroxide
- The presence of 'clue' cells on microscopic examination of the vaginal fluid.

Clue cells are squamous epithelial cells from the vagina, which have bacteria adherent to their surface, giving a granular appearance to the cell. A Gram stain gives a typical reaction of partial stain uptake.

Treatment

Metronidazole given orally in doses of 400 mg twice daily for 5–7 days is usually recommended. A single dose of 2 g metronidazole is less effective. Topical 2% clindamycin cream 5 g intravaginally once daily for 7 days is effective.

Recurrence is high, with some studies giving a rate of 80% within 9 months of completing metronidazole therapy. There is debate over the treatment of asymptomatic women who fulfil the diagnostic criteria for BV. Until the relevance of BV to other pelvic infections is elucidated, the treatment of asymptomatic women with BV is not to be recommended. Simultaneous treatment of the male partner does not

influence the rate of recurrence of BV and routine treatment of male partners is not indicated.

INFESTATIONS (see also Chapter 24)

Pediculosis pubis

The pubic louse (*Phthirus pubis*) is a blood-sucking insect which attaches tightly to the pubic hair. They may also attach to eyelashes and eyebrows. It is relatively host-specific and is transferred only by close bodily contact. Eggs (nits) are laid at hair bases and usually hatch within a week. Although infestation may be asymptomatic, the most common complaint is of itch.

Diagnosis

Lice may be seen on the skin at the base of pubic and other body hairs. They resemble small scabs or freckles but if they are picked up with forceps and placed on a microscope slide, will move and walk away. Blue macules may be seen at the feeding sites. Nits are usually closely adherent to hairs. Both are highly characteristic under the low-power microscope.

As with all sexually transmitted infections, the patient must be screened for co-existing pathogens.

Treatment

Both lice and eggs must be killed with 0.5% malathion, 1% permethrin or 0.5% carbaryl. The preparation should be applied to all areas of the body from the neck down and washed off after 12 h. In a few cases, a further application after 1 week may be necessary. For severe infestations, antipruritics may be indicated for the first 48 h. All sexual partners should be seen and screened.

Scabies

This is discussed in Chapter 24.

HUMAN IMMUNE DEFICIENCY VIRUS (HIV) AND AIDS

Epidemiology

Since the first description of AIDS in 1981 and the identification of the causative organism HIV in 1984, more than 20 million people have died. At least 33 million people worldwide are living with HIV infection. Sub-Saharan Africa remains the most seriously affected, but in some areas, the number of new diagnoses has stabilized. However, in Eastern Europe and parts of central Asia, infection rates are rising exponentially. The human, societal and economic costs are huge: 33% of 15-year-olds in high-prevalence countries in Africa will die of HIV. Demographics of the epidemic have varied greatly, influenced by social, behavioural, cultural and political factors. Highly active antiretroviral therapy (HAART) has dramatically reduced mortality for those who are able to access care. Current global estimates suggest that about a quarter of those who need HAART are on treatment but that for each individual starting therapy there are two new infections, highlighting the size of the problem and the global inequalities that exist in healthcare.

In the UK falling death rates and continued new infections mean that the total number of people living with HIV continues to rise. Men who have sex with men (MSM) and culturally diverse heterosexual populations from sub-Saharan Africa,

are the two largest groups of people living with HIV in the UK, and accessing treatment and care. Of those diagnosed with HIV in the UK, 30% are women. As mortality rates fall so the population of people with HIV is becoming older, further changing the clinical picture.

Approximately one-quarter of those with HIV infection in the UK are undiagnosed and unaware of their infection, which contributes to late diagnosis, poorer clinical outcomes and onward transmission. Late diagnosis is now the most common cause of HIV-related morbidity and mortality in the UK. Reducing undiagnosed HIV through wider testing, particularly in patients presenting with clinical conditions that are associated with HIV and in areas with high seroprevalence, is critical to both the individual and public health (Box 4.21).

Routes of acquisition

Despite the fact that HIV can be isolated from a wide range of body fluids and tissues, the majority of infections are transmitted via semen, cervical secretions and blood.

- **Sexual intercourse (vaginal and anal).** Globally, heterosexual intercourse accounts for the vast majority of infections and co-existent STIs, especially those causing genital ulceration, enhance transmission. Passage of HIV appears to be more efficient from men to women and to the receptive partner in anal intercourse, than vice versa. In the UK, sex between men accounts for over half the infections reported, but there is an increasing rate of heterosexual transmission. In Central and sub-Saharan Africa, the epidemic has always been heterosexual and more than half the infected adults in these regions are women. South-east Asia and the Indian subcontinent are experiencing an explosive epidemic, driven by heterosexual intercourse and a high incidence of other sexually transmitted diseases.
- **Mother-to-child (transplacental, perinatal, breast-feeding).** Vertical transmission is the most common route of HIV infection in children. European studies suggest that, without intervention, 15% of babies born to HIV-infected mothers are likely to be infected, although rates of up to 40% have been reported from Africa and the USA. Increased vertical transmission is associated with advanced disease in the mother, maternal viral load, prolonged and premature rupture of membranes and chorioamnionitis. Transmission can occur *in utero*, although the majority of infections take place perinatally. Breast-feeding has been shown to double the risk of vertical transmission. In the developed world, interventions to reduce vertical transmission, including the use of antiretroviral agents and the avoidance of breast-feeding, have led to a dramatic fall in the numbers of infected children. The lack of access to these interventions in resource-poor countries in which 90% of infections occur is a major issue.
- **Contaminated blood, blood products and organ donations.** Screening of blood and blood products was introduced in 1985 in Europe and North America. Prior to this, HIV infection was associated with the use of clotting factors (for haemophilia) and with blood transfusions. In some parts of the world where blood products may not be screened and in areas where the rate of new HIV infections is very high, transfusion-associated transmission continues to occur.
- **Contaminated needles (intravenous drug misuse, injections, needle-stick injuries).** The practice of sharing needles and syringes for intravenous drug use

Box 4.21 HIV testing: UK guidelines on where and who to test

1. Universal: Clinical settings in which all patients should be offered HIV testing:

- GUM/sexual health clinics
- Antenatal services
- Termination of pregnancy services
- Drug dependency programmes
- Healthcare services for tuberculosis, hepatitis B, hepatitis C and lymphoma

2. People in whom HIV testing is recommended

- All patients diagnosed with a sexually transmitted infection
- Sexual partners of men and women known to be HIV positive
- Men who have disclosed sexual contact with other men
- Female sexual contacts of men who have sex with men
- People reporting a history of injecting drug use
- Men and women known to be from a country of high HIV prevalence (>1%)
- Men and women who report sexual contact abroad or in the UK with individuals from countries of high HIV prevalence
- Patients presenting for healthcare where HIV enters the differential diagnosis (see below for table of indicator conditions)

HIV-associated indicator conditions

Respiratory

Tuberculosis; pneumocystis^a; bacterial pneumonia; aspergillosis.

Neurology

Cerebral toxoplasmosis^a; primary cerebral lymphoma^a; cryptococcal meningitis^a; progressive multifocal leucoencephalopathy^a; aseptic meningitis/encephalitis; cerebral abscess; space-occupying lesion of unknown cause; Guillain-Barré syndrome; transverse myelitis; peripheral neuropathy; dementia.

Dermatology

Kaposi's sarcoma^a; severe/recalcitrant seborrhoeic dermatitis; severe/recalcitrant psoriasis; multidermatomal/recurrent herpes zoster.

Gastroenterology

Persistent cryptosporidiosis^a; oral candidiasis; oral hairy leukoplakia; chronic diarrhoea of unknown cause; weight loss of unknown cause; *Salmonella*; *Shigella*; *Campylobacter*; hepatitis B infection; hepatitis C infection.

Oncology

Non-Hodgkin's lymphoma^a; anal cancer; anal intraepithelial dysplasia; lung cancer; seminoma; head and neck cancer; Hodgkin's lymphoma; Castleman's disease.

Gynaecology

Cervical cancer^a; vaginal intraepithelial neoplasia; cervical intraepithelial neoplasia, grade 2 or above.

Haematology

Any unexplained blood dyscrasia including thrombocytopenia, neutropenia and lymphopenia.

Ophthalmology

Cytomegalovirus retinitis^a; infective retinal diseases including herpesviruses and toxoplasma; any unexplained retinopathy.

ENT

Lymphadenopathy of unknown cause; chronic parotitis; lymphoepithelial parotid cysts.

Other

Mononucleosis-like syndrome (primary HIV infection); pyrexia of unknown origin; any lymphadenopathy of unknown cause; any sexually transmitted infection.

^aAIDS-defining condition.

<http://guidance.nice.org.uk/PH33>; <http://www.nice.org.uk/guidance/PH34>; <http://www.bhiva.org/HIVTesting2008.aspx>

continues to be a major route of transmission of HIV in both developed countries and parts of South-east Asia, Latin America and the states of the former Soviet Union. In some areas, including the UK, successful education and needle exchange schemes have reduced the rate of transmission by this route. Iatrogenic transmission from needles and syringes used in developing countries is reported. Healthcare workers have a risk of approximately 0.3% following a single needle-stick injury with known HIV-infected blood.

There is no evidence that HIV is spread by social or household contact or by blood-sucking insects such as mosquitoes and bed bugs.

The virus

HIV belongs to the lentivirus group of the retrovirus family. There are two types, HIV-1 and HIV-2. HIV-1 is the most frequently occurring strain globally. HIV-2 is almost entirely confined to West Africa, although there is some spread to Europe, particularly France and Portugal. HIV-2 has only 40% structural homology with HIV-1 and although it is associated with immunosuppression and AIDS, appears to take a more indolent course than HIV-1. Many of the drugs that are used in HIV-1 are ineffective in HIV-2. The structure of HIV is shown in Figure 4.41.

Retroviruses are characterized by the possession of the enzyme reverse transcriptase, which allows viral RNA to be transcribed into DNA and thence incorporated into the host cell genome. Reverse transcription is an error-prone process with a significant rate of mis-incorporation of bases. This, combined with a high rate of viral turnover, leads to considerable genetic variation and a diversity of viral subtypes or clades. On the basis of DNA sequencing, HIV-1 is divided into four distinct strains, which represent four independent cross species transfers, three (M, N and O) based on the chimpanzee related strains of SIV and 1 (P) that may represent chimpanzee to gorilla to human transmission.

Figure 4.41 Structure of HIV. Two molecules of single-stranded RNA are shown within the nucleus. The reverse transcriptase polymerase converts viral RNA into DNA (a characteristic of retroviruses). The protease includes integrase (p32 and p10). The p24 (core protein) levels can be used to monitor HIV disease. p17 is the matrix protein; gp120 is the outer envelope glycoprotein which binds to cell surface CD4 molecules; gp41, a transmembrane protein, influences infectivity and cell fusion capacity.

- **Group M (major) subtypes** (98% of infections worldwide) exhibit a high degree of diversity, with subtypes (or clades), denoted A–K. There is a predominance of subtype B in Europe, North America and Australia, but areas of Central and sub-Saharan Africa have multiple M subtypes, with clade C being the commonest subtype. Recombination of viral material generates an array of circulating recombinant forms (CRFs), which increases the genetic diversity that may be encountered.
- **Group N (new)** is mostly confined to parts of West Central Africa (e.g. Gabon).
- **Group O (outlier) subtypes** are highly divergent from group M and are largely confined to small numbers centred on Cameroon.
- **Group P** related to gorilla strains of SIV has been identified from a patient from Cameroon.

Connections between genetic diversity and biological effects, in particular pathogenicity, rates of transmission and response to therapy are being sought. Diversity in the viral subtypes and recombinant forms encountered in the UK is increasing.

Pathogenesis

The interrelationship between HIV and the host immune system is the basis of the pathogenesis of HIV disease. At the time of initial exposure virus is transported by dendritic cells from mucosal surfaces to regional lymph nodes where permanent infection is established. The host cellular receptor that is recognized by HIV surface glycoprotein gp120 is the CD4 molecule, which defines the cell populations that are susceptible to infection (Fig. 4.42). The interaction between CD4 and HIV gp120 surface glycoprotein, together with host chemokine CCR5 co-receptors, is responsible for HIV entry into cells. Although CCR5 CD4 memory T lymphocytes within all body systems are susceptible to infection and depletion those found in the gastrointestinal tract are heavily infected early in the process and become rapidly depleted leading to compromised mucosal immune function.

Studies of viral turnover have demonstrated a virus half-life in the circulation of about 6 hours. To maintain observed levels of plasma viraemia, 10^8 – 10^9 virus particles need to be released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell, owing to direct HIV effects, linking HIV replication to the process of CD4 destruction and depletion. Loss of activated CD4 T lymphocytes is a key factor in the immunopathogenesis of HIV, but debate continues about the exact mechanisms of cell depletion.

Resulting cell-mediated immunodeficiency leaves the host open to infections with intracellular pathogens, while co-existing antibody abnormalities predispose to infections with capsulated bacteria. HIV is associated with a long-term inflammatory state, which is a key driver of disease progression. T-cell activation is observed from the earliest stages of infection which in turn leads to an increase in the numbers of susceptible CD4 bearing target cells that can become infected and destroyed. This inflammatory state is associated with HIV itself, with co-pathogens such as cytomegalovirus and with the translocation of microbial products, in particular lipopolysaccharides, from the gut into the systemic circulation following HIV destruction of normal mucosal immunity. Raised levels of inflammatory cytokines and coagulation system activation occur. These inflammatory responses play a role in HIV-associated end organ damage.

Figure 4.42 HIV entry and replication in CD4 T lymphocytes. (1) Binding: the virus binds to host CD4 receptor molecules via the envelope glycoprotein gp 120 and co-receptors CCR5 and CXCR4. (2) Fusion: a subsequent conformational change results in the fusion between gp41 and the cell membrane. (3) Reverse transcription: entry of the viral capsid is followed by the uncoating of the RNA. DNA copies are made from both RNA templates. DNA polymerase from the host cell leads to formation of dsDNA. (4) Integration: in the nucleus, virally encoded DNA is inserted into the host genome. (5) Transcription: regulatory proteins control transcription (an RNA molecule is now synthesized from the DNA template). (6) Budding: the virus is reassembled in the cytoplasm and budded out from the host cell.

Diagnosis and natural history (see Fig. 4.43)

HIV is now a manageable chronic condition, but only in those who are aware of their diagnosis and who start effective antiretroviral therapy early enough. Starting treatment with more advanced disease compromises clinical outcomes. In 2009, 26% of those living with HIV in the UK were unaware of their infection. More than half of those newly diagnosed in the UK in 2009 were 'late presenters', i.e. had a CD4 count below the threshold to start therapy (<350 cells/mm³), and in one-third, the CD4 count was below 200 cells/mm³ putting them at high risk of HIV-associated pathology. Increasing the uptake of HIV testing is a major public health objective. Guidelines on HIV testing from The British HIV Association and the National Institute for Health and Clinical Excellence (NICE) include clinical settings in which HIV testing should be universally offered, together with a list of clinical situations and diagnoses (indicator conditions) that are highly predictive of HIV infection and where HIV testing should be recommended (Box 4.21). All new registrants in primary care and patients admitted to acute medical care should be recommended to test in areas of the UK where HIV seroprevalence is $>2/1000$ population.

Discussion about HIV testing and the consent required is straightforward and should be within the competencies of a wide range of healthcare professionals. Sensitive and specific point-of-care HIV antibody tests using either blood or

oral fluids can give results within minutes and have extended the possibilities for diagnosis. All reactive point-of-care tests should be followed up with confirmatory serological assays, appropriate arrangements made to ensure patients receive test results and those who are found to be HIV positive have rapid routes into specialist care.

The tests

HIV infection is diagnosed either by the detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material. The recommended UK first-line assay is one which tests for HIV antibody AND p24 antigen simultaneously. These fourth generation assays have the advantage of reducing the time between infection and an HIV-positive test result to one month which is several weeks earlier than with sensitive third generation (antibody only detection) assays.

Detection of IgG antibody to envelope components.

This is the most commonly used marker of infection. The routine tests used for screening are based on ELISA techniques, which may be confirmed with Western blot assays. Up to 3 months (mean 6 weeks) may elapse from initial infection to antibody detection (serological latency, or window period). These antibodies to HIV have no protective function and persist for life. As with all IgG antibodies, anti-HIV will cross the placenta. All babies born to HIV-infected women will thus have the antibody at birth. In this situation, anti-HIV

antibody is not a reliable marker of active infection and in uninfected babies will be gradually lost over the first 18 months of life.

Simple and rapid HIV antibody assays are increasingly available, giving results within minutes. Assays that can utilize alternative body fluids to serum/plasma such as oral fluid, whole blood and urine are now available and home testing kits are being developed. These tests are extremely sensitive and may give false-positive results, making it necessary to perform a confirmatory test.

A Serologic Testing Algorithm for Recent HIV Seroconversions (STARHS) can be used to identify recently acquired infection. A highly sensitive ELISA that is able to detect HIV antibodies 6–8 weeks after infection is used on blood in patients with positive oral fluid test, in parallel with a less sensitive (detuned) test that identifies later HIV antibodies within 130 days. A positive result on the sensitive test and a negative 'detuned' test are indicative of recent infection, while positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemiological surveillance and monitoring.

IgG antibody to p24 (anti-p24). This can be detected from the earliest weeks of infection and through the asymptomatic phase. It is frequently lost as the disease progresses.

Genome detection assays. Nucleic acid-based assays that amplify and test for components of the HIV genome are available. These assays are used to aid diagnosis of HIV in the babies of HIV-infected mothers or in situations where serological tests may be inadequate, such as in early infection when antibody may not be present, or in subtyping HIV variants for medicolegal reasons. (See the discussion of viral load monitoring, on p. 179.)

Viral p24 antigen (p24ag). This is detectable shortly after infection but has usually disappeared by 8–10 weeks after exposure. It can be a useful marker in individuals who have been infected recently but have not had time to mount an antibody response.

Isolation of virus in culture. This is a specialized technique available in some laboratories to aid diagnosis and as a research tool.

Clinical features of HIV infection

The spectrum of illnesses associated with HIV infection is broad and is the result of direct HIV effects, HIV-associated immune dysfunction, the drugs used to treat the condition, as well as co-existing morbidity and co-infections.

Several classification systems exist; the most widely used being the 1993 Centers for Disease Control (CDC) classification (Box 4.22). This classification depends to a large extent on definitive diagnoses of infection, which makes it more

difficult to use in those areas of the world without sophisticated laboratory support.

As immunosuppression progresses, the patient is susceptible to an increasing range of opportunistic infections and tumours, certain of which meet the criteria for the diagnosis of AIDS (Box 4.23).

The definition of AIDS differs between the USA and Europe. The USA definition includes individuals with CD4 counts below 200 in addition to the clinical classification based on the presence of specific indicator diagnoses shown in Box 4.22. In Europe, the definition remains based on the diagnosis of specific clinical conditions with no inclusion of CD4 lymphocyte counts. Where highly active antiretroviral therapy (HAART) is available and started before the development of severe immunosuppression, progression to AIDS is now uncommon.

Incubation, seroconversion and primary illness

Primary HIV infection (PHI) refers to the first 6-month period following HIV acquisition. This is a period of uncontrolled

Box 4.23 AIDS-defining conditions

- Candidiasis of bronchi, trachea or lungs
- Candidiasis, oesophageal
- Cervical carcinoma, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (1-month duration)
- Cytomegalovirus (CMV) disease (other than liver, spleen or nodes)
- CMV retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex, chronic ulcers (1-month duration); or bronchitis, pneumonitis or oesophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis; chronic intestinal (1-month duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma (primary) of brain
- *Mycobacterium avium-intracellulare* complex or *M. kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jirovecii* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leucoencephalopathy
- *Salmonella* septicaemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome, due to HIV

Box 4.22 Summary of CDC classification of HIV infection

Absolute CD4 count (/mm ³)	A Asymptomatic or persistent generalized lymphadenopathy or acute seroconversion illness	B HIV-related conditions, ^a not A or C	C Clinical conditions listed in AIDS surveillance case definition (see Box 4.23)
>500	A1	B1	C1
200–499	A2	B2	C2
<200	A3	B3	C4

^aExamples of category B conditions include: bacillary angiomatosis; candidiasis (oropharyngeal); constitutional symptoms; oral hairy leucoplakia; herpes zoster involving more than one dermatome; idiopathic thrombocytopenic purpura; listeriosis, pelvic inflammatory disease, especially if complicated by tubo-ovarian abscess; peripheral neuropathy.

viral replication resulting in high levels of HIV circulating in the plasma and genital tract and consequently of high infectiousness. At a population level PHI is increasingly recognized as a contributor to onward transmission. In the UK up to 20% of all newly diagnosed individuals are recently infected. The 2–4 weeks immediately following infection may be silent both clinically and serologically. In a number of people, a self-limiting nonspecific illness occurs 3–6 weeks after exposure. Symptoms include fever, arthralgia, myalgia, lethargy, lymphadenopathy, sore throat, mucosal ulcers and occasionally a transient faint pink maculopapular rash. Neurological symptoms are common, including headache, photophobia, myelopathy and neuropathy and in rare cases encephalopathy. The illness lasts up to 3 weeks and recovery is usually complete.

Laboratory abnormalities include lymphopenia with atypical reactive lymphocytes noted on blood film, thrombocytopenia and raised liver transferases. CD4 lymphocytes may be markedly depleted and the CD4:CD8 ratio reversed. Antibodies to HIV may be absent during this early stage of infection, although the level of circulating viral RNA is high and p24 core protein may be detectable. HIV RNA NAAT assays may be diagnostic 7 days before a p24 antigen test and 12 days before a sensitive HIV antibody test. If PHI is suspected but standard diagnostic tests are negative then repeat testing in 7 days and referral for expert advice is recommended.

Clinical latency

The rate of clinical progression of untreated HIV is variable. The majority of people with HIV infection are asymptomatic for a substantial but variable length of time. However, the virus continues to replicate and the person is infectious. Most people with HIV have a gradual decline in CD4 count over a period of approximately 10 years before progression to AIDS. Others progress much more rapidly, with continued high levels of viral RNA and a rapid decline in CD4 count over 2–5 years. Other, long-term non-progressors, may continue with a normal CD4 count over many years. Within this group, a small subpopulation of elite controllers maintain a viral load below 2000 copies/mL or even to undetectable levels without therapy.

Older age is associated with more rapid progression. Gender and pregnancy *per se* do not appear to influence the rate of progression, although women may fare less well for a variety of reasons. A subgroup of patients with asymptomatic infection have *persistent generalized lymphadenopathy* (PGL), defined as lymphadenopathy (>1 cm) at two or more extra-inguinal sites for more than 3 months in the absence of causes other than HIV infection. The nodes are usually symmetrical, firm, mobile and non-tender. There may be associated splenomegaly. The architecture of the nodes shows hyperplasia of the follicles and proliferation of the capillary endothelium. Biopsy is rarely indicated. Similar disease progression has been noted in asymptomatic patients with or without PGL. Nodes may disappear with disease progression.

Symptomatic HIV infection

As HIV infection progresses, the viral load rises, the CD4 count falls and the patient develops an array of symptoms and signs. The clinical picture is the result of direct HIV effects and of the associated immunosuppression.

In an individual patient, the clinical consequences of HIV-related immune dysfunction will depend on at least three factors:

- The *microbial exposure of the patient throughout life*. Many clinical episodes represent reactivation of previously acquired infection, which has been latent. Geographical factors determine the microbial repertoire of an individual patient. Those organisms requiring intact cell-mediated immunity for their control are most likely to cause clinical problems.
- The *pathogenicity of organisms encountered*. High-grade pathogens such as *Mycobacterium tuberculosis*, *Candida* and the herpesviruses are clinically relevant even when immunosuppression is mild and will thus occur earlier in the course of the disease. Less virulent organisms occur at later stages of immunodeficiency.
- The *degree of immunosuppression of the host*. When patients are severely immunocompromised (CD4 count <100/mm³) disseminated infections with organisms of very low virulence such as *M. avium-intracellulare* (MAI) and *Cryptosporidium* are able to establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

Effects of HIV infection

Neurological disease

Infection of the nervous tissue occurs at an early stage but clinical neurological involvement increases as HIV advances. This includes *AIDS dementia complex* (ADC), *sensory polyneuropathy* and *aseptic meningitis* (see p. 1130). These conditions are much less common since the introduction of HAART (highly active antiretroviral therapy). The pathogenesis is thought to be due both to the release of neurotoxic products by HIV itself and to cytokine abnormalities secondary to immune dysregulation.

ADC has varying degrees of severity, ranging from mild memory impairment and poor concentration through to severe cognitive deficit, personality change and psychomotor slowing. Changes in affect are common and depressive or psychotic features may be present. The spinal cord may show vacuolar myelopathy histologically. In severe cases brain CT scan shows atrophic change of varying degrees. MRI changes consist of white matter lesions of increased density on T2-weighted sections. EEG shows non-specific changes consistent with encephalopathy. The CSF is usually normal, although the protein concentration may be raised. Patients with mild neurological dysfunction may be unduly sensitive to the effects of other insults such as fever, metabolic disturbance or psychotropic medication, any of which may lead to a marked deterioration in cognitive functioning.

Sensory polyneuropathy is seen in advanced HIV infection, mainly in the legs and feet, although hands may be affected. Severe forms cause intense pain, usually in the feet, which disrupts sleep, impairs mobility and generally reduces the quality of life.

Autonomic neuropathy may also occur with postural hypotension and diarrhoea. Autonomic nerve damage is found in the small bowel. Didanosine and stavudine produce a similar neuropathy as a major toxic side-effect and are best avoided in patients with HIV neuropathy.

HAART, using agents that penetrate the CNS can lead to significant improvements in cognitive function in many patients with ADC. It may also have a neuroprotective role.

Table 4.51 Some mucocutaneous manifestations of HIV infection (see also Ch. 24)

Skin	Mucous membranes
Dry skin and scalp	Candidiasis:
Onychomycosis	oral
Seborrhoeic dermatitis	vulvovaginal
Tinea:	Oral hairy leucoplakia
cruris	Aphthous ulcers
pedis	Herpes simplex:
Pityriasis:	genital
versicolor	oral
rosea	labial
Folliculitis	Periodontal disease
Acne	Warts:
Molluscum contagiosum	oral
Warts	genital
Herpes zoster:	
multidermatomal	
disseminated	
Papular pruritic eruption	
Scabies	
Ichthyosis	
Kaposi's sarcoma	

Eye disease

Eye pathology is usually seen in the later stages. The most serious is cytomegalovirus retinitis (see p. 81), which is sight-threatening. Retinal cotton wool spots due to HIV *per se* are rarely troublesome but they can be confused with CMV retinitis. Anterior uveitis can present as acute red eye associated with rifabutin therapy for mycobacterial infections in HIV. Steroids used topically are usually effective but modification of the dose of rifabutin is required to prevent relapse. Pneumocystis, toxoplasmosis, syphilis and lymphoma can all affect the retina and the eye may be the site of first presentation.

Mucocutaneous manifestations (Table 4.51)

The skin is a common site for HIV-related pathology as the function of dendritic and Langerhans' cells, both target cells for HIV, is disrupted. Delayed-type hypersensitivity, a good indicator of cell-mediated immunity, is frequently reduced or absent even before clinical signs of immunosuppression appear. Pruritus is a common complaint at all stages of HIV. Generalized dry, itchy, flaky skin is typical and the hair may become thin and dry. An intensely pruritic papular eruption favouring the extremities may be found, particularly in patients from African backgrounds. Eosinophilic folliculitis presents with urticarial lesions particularly on the face, arms and legs.

Drug reactions with cutaneous manifestations are frequent; with rashes developing notably to sulphur-containing drugs amongst others (see Fig. 24.39). Recurrent aphthous ulceration, which is severe and slow to heal, is common and can impair the patient's ability to eat. Biopsy may be indicated to exclude other causes of ulceration. Topical steroids are useful and resistant cases may respond to thalidomide. In addition to the above the skin is a common site of opportunistic infections (see p. 127).

Haematological complications

These are common in advanced HIV infection.

- **Lymphopenia** progresses as the CD4 count falls.
- **Anaemia of chronic HIV infection** is usually mild, normochromic and normocytic.
- **Neutropenia** is common and usually mild.

- **Isolated thrombocytopenia** may occur early in infection and be the only manifestation of HIV for some time. Platelet counts are often moderately reduced but can fall dramatically to $10\text{--}20 \times 10^9/\text{L}$ producing easy bleeding and bruising. Circulating antiplatelet antibodies lead to peripheral destruction. Megakaryocytes are increased in the bone marrow but their function is impaired. Effective antiretroviral therapy usually produces a rise in platelet count. Thrombocytopenic patients undergoing dental, medical or surgical procedures may need therapy with human immunoglobulin, which gives a transient rise in platelet count, or be given platelet transfusion. Steroids are best avoided.
- **Pancytopenia** occurs because of underlying opportunistic infection or malignancies, in particular *Mycobacterium avium-intracellulare*, disseminated cytomegalovirus and lymphoma.
- **Other complications.** Myelotoxic drugs include zidovudine (megaloblastic anaemia, red cell aplasia, neutropenia); lamivudine (anaemia, neutropenia); ganciclovir (neutropenia); systemic chemotherapy (pancytopenia) and co-trimoxazole (agranulocytosis).

Gastrointestinal effects (see p. 295)

Weight loss and diarrhoea are common in untreated HIV-infected patients. Wasting is a common feature of advanced HIV infection, which although originally attributed to direct HIV effects on metabolism, is usually a consequence of anorexia. There is a small increase in resting energy expenditure in all stages of HIV, but weight and lean body mass usually remain normal during periods of clinical latency when the patient is eating normally.

Gastrointestinal infections are common. An HIV enteropathy with varying degrees of villous atrophy has been described with chronic diarrhoea when no other pathogen has been found.

Hypochlorhydria is reported in patients with advanced HIV disease and may have consequences for drug absorption and bacterial overgrowth in the gut.

Rectal lymphoid tissue cells are the targets for HIV infection during penetrative anal sex and may be a reservoir for infection to spread through the body.

Renal complications

HIV-associated nephropathy (HIVAN) (see p. 588), although rare, can cause significant renal impairment, particularly in more advanced disease. It is most frequently seen in black male patients and can be exacerbated by heroin use.

Nephrotic syndrome subsequent to focal glomerulosclerosis is the usual pathology, which may be a consequence of HIV cytopathic effects on renal tubular epithelium. The course is usually relentlessly progressive and dialysis may be required.

Many nephrotoxic drugs are used in the management of HIV-associated pathology, particularly foscarnet, amphotericin B, pentamidine and sulfadiazine. Tenofovir is associated with Fanconi's syndrome (p. 1040).

Respiratory complications

The upper airway and lungs serve as a physical barrier to air-borne pathogens and any damage will decrease the efficiency of protection, leading to an increase in upper and lower respiratory tract infections. The sinus mucosa may also function abnormally in HIV infection and is frequently the site of chronic inflammation. Response to antibacterial therapy

and topical steroids is usual but some patients require surgical intervention. A similar process is seen in the middle ear, which can lead to chronic otitis media.

Lymphoid interstitial pneumonitis (LIP) is well described in paediatric HIV infection but is uncommon in adults. There is an infiltration of lymphocytes, plasma cells and lymphoblasts in alveolar tissue. Epstein–Barr virus may be present. The patient presents with dyspnoea and a dry cough, which may be confused with pneumocystis infection (see p. 1040). Reticular nodular shadowing is seen on chest X-ray. Therapy with steroids may produce clinical and histological benefit in some patients.

Endocrine complications

Various endocrine abnormalities have been reported, including reduced levels of testosterone and abnormal adrenal function. The latter assumes clinical significance in advanced disease when intercurrent infection superimposed upon borderline adrenal function precipitates clear adrenal insufficiency requiring replacement doses of glucocorticoid. CMV is also implicated in adrenal-deficient states.

Cardiac complications

Cardiovascular pathology is increasingly recognized as a cause of morbidity in people with HIV. Although lipid dysregulation has been associated with antiretroviral medication (ARV), the observation has been made that HDL levels are lower in those with untreated HIV infection than in HIV-negative controls. In a large international study (SMART), ischaemic heart disease was more common in those who took intermittent ARV therapy than in those who maintained viral suppression. Cardiomyopathy, although rare, is associated with HIV and may lead to congestive cardiac failure. Lymphocytic and necrotic myocarditis have been described. Ventricular biopsy should be performed to ensure other treatable causes of myocarditis are excluded.

Conditions associated with HIV immunodeficiency

Immunodeficiency (see p. 81) allows the development of opportunistic infections (OI) (Table 4.52 and see also Table 4.56). These are diseases caused by organisms that are not usually considered pathogenic, unusual presentations of known pathogens and the occurrence of tumours that may have an oncogenic viral aetiology. Susceptibility increases as the patient becomes more immunosuppressed. CD4 T lymphocyte numbers are used as markers to predict the risk of infection. Patients with CD4 counts above 200 are at low risk for the majority of AIDS-defining OIs. A hierarchy of thresholds for specific infectious risks can be constructed. Mechanisms include defective T cell function against protozoa, fungi and viruses, impaired macrophage function against intracellular bacteria such as *Mycobacteria* and *Salmonella* and defective B-cell immunity against capsulated bacteria such as *Strep. pneumoniae* and *Haemophilus*. Many of the organisms causing clinical disease are ubiquitous in the environment or are already carried by the patient.

Diagnosis in an immunosuppressed patient may be complicated by a lack of typical signs, as the inflammatory response is impaired. Examples are lack of neck stiffness in cryptococcal meningitis or minimal clinical findings in early *Pneumocystis jiroveci* pneumonia. Multiple pathogens may co-exist. Indirect serological tests are frequently unreliable. Specimens should be obtained from the appropriate site for examination and culture in order to make a diagnosis.

Table 4.52 Major HIV-associated pathogens

Protozoa

Toxoplasma gondii
Cryptosporidium parvum
Microsporidia spp.
Leishmania donovani
Isospora belli

Viruses

Cytomegalovirus
 Herpes simplex
 Varicella zoster
 Human papillomavirus
 JC polyoma virus

Fungi and yeasts

Pneumocystis jiroveci
Cryptococcus neoformans
Candida spp.
Dermatophytes (*Trichophyton*)
Aspergillus fumigatus
Histoplasma capsulatum
Coccidioides immitis

Bacteria

Salmonella spp.
Mycobacterium tuberculosis
M. avium-intracellulare
Streptococcus pneumoniae
Staphylococcus aureus
Haemophilus influenzae
Moraxella catarrhalis
Rhodococcus equi
Bartonella quintana
Nocardia

Investigations and monitoring of HIV-infected patients

Initial assessment

Newly diagnosed patients should be reviewed by an HIV clinician within 2 weeks of diagnosis, or earlier if the patient is symptomatic or has other acute needs. A full medical history, physical examination and laboratory evaluation should be undertaken in all newly diagnosed patients to determine the stage of infection, the presence of co-morbidities and co-infections and to assess overall physical, mental and sexual health. The initial assessment should also include details of socioeconomic situation, relationships, family and social support networks and substance misuse. Baseline investigations will depend on the clinical setting, but those appropriate for an asymptomatic person in the UK are shown in Box 4.24.

Monitoring

Patients are regularly monitored (approximately 3-monthly) to assess the progression of the infection and the need for treatment. Decisions about appropriate intervention can be made.

Immunological monitoring

CD4 lymphocytes. The absolute CD4 count and its percentage of total lymphocytes falls as HIV progresses. These figures bear a relationship to the risk of the occurrence of HIV-related pathology, with patients with counts below 200 cells at greatest risk. Rapidly falling CD4 counts and those below 350 are an indication for HAART. Factors other than HIV (e.g. smoking, exercise, intercurrent infections and diurnal variation) also affect CD4 numbers. CD4 counts are performed at approximately 3-monthly intervals unless values are approaching critical levels for intervention, in which case they are performed more frequently.

Box 4.24 Baseline assessment for a newly diagnosed asymptomatic patient with HIV infection
Haematology

- Full blood count, differential count and film

Biochemistry

- Serum, liver and renal function including eGFR
- Fasting serum lipid profile, total cholesterol, HDL cholesterol
- Fasting blood glucose
- Serum bone profile including 25 OH vitamin D
- Urinalysis
- Dipstick for blood, protein and glucose
- Urine protein/creatinine ratio

Immunology

- Lymphocyte subsets (repeat to confirm baseline within 1–3 months)
- HLA B*5701 status

Virology

- HIV antibody (confirmatory)
- HIV viral load
- HIV genotype and subtype determination
- Hepatitis A IgG
- Hepatitis B surface antigen and full profile
- Hepatitis C antibody (followed by hepatitis C RNA testing if antibody positive and confirmation of antibody positive status if RNA negative)

Microbiology

- Toxoplasmosis serology
- Syphilis serology
- Screen for other sexually transmitted infections

Other

- Cervical cytology
- Chest X-ray if indicated
- 10-year cardiovascular risk assessment
- Fracture risk assessment

Figure 4.43 The immune response to HIV (seroconversion).

HIV RNA is the standard marker of treatment efficacy (see below). Both duration and magnitude of virus suppression are pointers to clinical outcome. None of the available therapies appears to be able to suppress viral replication indefinitely and a rising viral load, in a patient where compliance is assured, indicates drug failure.

Various guidelines exist for viral load monitoring in clinical practice. Baseline measurements are followed by repeat estimations at intervals of 3–4 months, ideally in conjunction with CD4 counts to allow both pieces of evidence to be used together in decision-making. Following initiation of antiretroviral therapy or changes in therapy, effects on viral load should be seen by 4 weeks, reaching a maximum at 10–12 weeks, when repeat viral load testing should be carried out (Fig. 4.43).

Genotype determination

Clear genotype variations exist within HIV, not only between viral subtypes but also with well-identified point mutations associated with resistance to antiretroviral drugs. New infections with drug-resistant variants of HIV may be seen. Viral genotype analysis is recommended for all newly diagnosed patients with HIV. The most appropriate sample is the one closest to the time of diagnosis and the results are used to guide the selection of HAART agents.

Management of the HIV-infected patient
(Box 4.25)

Effective ART has transformed the management of HIV infection with a movement away from treating opportunistic conditions in immunosuppressed patients towards delivering long-term, effective suppressive therapy. With access and adherence to potent, tolerable antiretroviral drugs within a managed clinical setting, a 35-year-old initiating therapy in the UK in 2011 has a life expectancy of about 40 years. Nevertheless, there is still no cure for HIV and patients live with a chronic, infectious and unpredictable condition. Limitations to efficacy include the inability of current drugs to clear HIV from certain intracellular pools, the occurrence of serious drug side-effects, adherence requirements, complex drug–drug interactions and the emergence of resistant viral strains.

The *aims of management* in HIV infection are to maintain physical and mental health, improve the quality of life, increase survival rates, restore and improve immune function, avoid onward transmission of the virus and to provide

Virological monitoring
Viral load (HIV RNA)

HIV replicates at a high rate throughout the course of infection, with many billion new virus particles being produced daily. The rate of viral clearance is relatively constant in any individual and thus the level of viraemia is a reflection of the rate of virus replication. This has both prognostic and therapeutic value.

The commonly used term ‘viral load’ encompasses viraemia and HIV RNA levels. Three *HIV RNA assays for viral load* are in current use:

- Branched-chain DNA (bDNA)
- Reverse transcription polymerase chain reaction (RT-PCR)
- Nucleic acid sequence-based amplification (NASBA).

Results are given in copies of viral RNA/mL of plasma, or converted to a logarithmic scale and there is good correlation between tests. The most sensitive test is able to detect as few as 20 copies of viral RNA/mL. Transient increases in viral load are seen following immunizations (e.g. for influenza and *Pneumococcus*) or during episodes of acute intercurrent infection (e.g. tuberculosis); and viral load measurements should not be carried out within a month of these events.

By about 6 months after seroconversion to HIV, the viral set-point for an individual is established and there is a correlation between HIV RNA levels and long-term prognosis, independent of the CD4 count. Those patients with a viral load consistently >100 000 copies/mL have a 10 times higher risk of progression to AIDS over the ensuing 5 years than those consistently below 10 000 copies/mL.

Box 4.25 An approach to sick HIV-positive patients

Potential problems include

- Adverse drug reactions
- Acute opportunistic infections
- Presentation or complication of malignancy
- Immune reconstitution phenomenon
- Infection in an immunocompromised host
- Organic or functional brain disorders
- Non-HIV-related pathology must not be forgotten

Full medical history

Remember:

- Antiretroviral drugs, prophylaxis, travel, previous HIV-related pathology, potential source of infectious agents (food hygiene, pets, contacts with acute infections, contact with TB, sexually transmitted infections)
- Secure confidentiality. Check with patient who is aware of HIV diagnosis

Full physical examination

Remember:

- Signs of adverse drug reactions, e.g. skin rashes, oral ulceration
- Signs of disseminated sepsis
- Clinical evidence of immunosuppression, e.g. oral candida, oral hairy leucoplakia
- Focal neurological signs and/or meningism
- Evidence of altered mental state – organic or functional
- Examine:
 - The genitalia, e.g. herpes simplex, syphilis, gonorrhoea
 - The fundi, e.g. CMV retinitis
 - The mouth
- Lymphadenopathy

Immediate investigations

- Full blood count and differential count
- Liver and renal function tests
- Plasma glucose
- Blood gases including acid–base balance
- Blood cultures, including specimens for mycobacterial culture
- Microscopy and culture of available/appropriate specimens: stool, sputum, urine, CSF
- Malaria screen in recent travellers from malaria areas
- Serological tests for cryptococcal antigen, toxoplasmosis: save serum for viral studies
- Chest X-ray
- CT/MR scan of brain if focal neurological signs and ALWAYS before lumbar puncture

Note: Lymphocyte subsets and HIV viral load assays may yield misleading results during intercurrent illness.

appropriate palliative support as needed. This requires long-term, maximal suppression of HIV activity using antiretroviral medication and management via a multidisciplinary team approach. Regular assessment is needed for details of intercurrent medical problems, medications, vaccinations, any recreational drug use, sexual history, reproductive decision-making, cervical cytology, social situation to include support networks, employment, benefits and accommodation. Depression and anxiety are common among people living with HIV and mood and cognitive function should be routinely assessed. Psychological support may be needed not only for the patient but also for family, friends and carers. Regular reviews of sexual and reproductive health together with advice on reducing the risk of HIV transmission must be provided and future sexual practices discussed. Information to allow people to make informed choices about childbearing is required. The implications for existing family members should be considered and diagnostic testing offered as

necessary. Regular monitoring of weight, body mass index, blood pressure and cardiovascular risk is required. Dietary assessment and advice should be freely accessible. General health promotion advice on smoking, alcohol, diet, drug misuse and exercise should be given, particularly in the light of the cardiovascular, metabolic and hepatotoxicity risks associated with HIV and its treatment.

Antiretroviral drugs (ARVs) (Table 4.53)

The treatment of HIV using antiretroviral therapy (HAART) continues to evolve and improve. Increased potency, reduced toxicity, greater convenience of formulation, compounds with different mechanisms of action coupled with improved understanding of drug resistance have combined to consistently improve HIV clinical outcome over time. An increase in the numbers of compounds, the array of drug–drug interactions, for example, combine to make HIV treatment complex and better clinical outcomes have been linked closely to physician expertise and the numbers of patients under direct care. Regularly updated treatment guidelines are produced in the UK by the British HIV Association (www.BHIVA.org.uk) and in the USA by the Department of Health and Human Services (<http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>). The most up-to-date versions can be found on these websites and the current version must be used.

The key practical principles of prescribing ARVs are given in Box 4.26.

Reverse transcriptase inhibitors

- **Nucleoside/nucleotide analogues.** Nucleoside reverse transcriptase inhibitors (NRTIs) inhibit the synthesis of DNA by reverse transcription and also act as DNA chain terminators. NRTIs need to be phosphorylated intracellularly for activity to occur. These were the first group of agents to be used against HIV, initially as monotherapy and later as dual drug combinations. Usually, two drugs of this class are combined to provide the ‘backbone’ of a HAART regimen. Several fixed-dose NRTI combinations are available, which helps reduce the pill burden. NRTIs have been associated with mitochondrial toxicity (see p. 186), a consequence of their effect on the human mitochondrial DNA polymerase. Lactic acidosis is a recognized complication of this group of drugs. Nucleotide analogues (nucleotide reverse transcriptase inhibitors (NtRTIs)) have a similar mechanism of action but only require two intracellular phosphorylation steps for activity (as opposed to the three steps for nucleoside analogues).
- **Non-nucleoside analogues.** Non-nucleoside reverse transcriptase inhibitors (NNRTIs) interfere with reverse transcriptase by direct binding to the enzyme. They are generally small molecules that are widely disseminated throughout the body and have a long half-life. NNRTIs affect cytochrome P450. They are ineffective against HIV-2. The level of cross-resistance across the class is very high. All have been associated with rashes and elevation of liver enzymes. Second-generation NNRTIs, such as etravirine and rilpivirine, with fewer adverse effects have some activity against viruses resistant to other compounds of the NNRTI class.

Protease inhibitors (PIs)

These act competitively on the HIV aspartyl protease enzyme, which is involved in the production of functional viral proteins

Table 4.53 Antiretroviral drugs generally used in clinical practice

	Drugs	Comments
Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)	Tenofovir, abacavir, zidovudine, ^a stavudine, ^a lamivudine, emtricitabine	Tenofovir is associated with renal and perhaps bone dysfunction. Abacavir is associated with hypersensitivity reactions in at-risk individuals (HLA B5701) and is associated in some studies with an increased risk of cardiovascular disease. Abacavir might be less potent than tenofovir in patients with high viral loads. Zidovudine and stavudine are associated with profound fat redistribution (lipoatrophy). All NRTIs are associated with potential to cause risk of severe lactic acidosis. The combination of tenofovir and emtricitabine is the preferred first-line regimen in most regions
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz, nevirapine, ^a efavirine	Efavirenz can cause CNS toxicity (which is usually time limited). Efavirenz has teratogenic potential and should be used with caution in woman who might become pregnant. Nevirapine can cause severe hepatotoxicity when used in patients with higher CD4 cell counts (more than 250 cells per μL for women and more than 400 cells per μL for men). Efavirine is given twice daily and has generally been used as second-line regimen
Integrase inhibitors	Raltegravir	Raltegravir has no short-term and no known long-term toxic effects, although data are scarce
Protease inhibitors	Fosamprenavir, atazanavir, darunavir, lopinavir, saquinavir (ritonavir)	Most protease inhibitors are extensively metabolised by the P450 CYP3A system; ritonavir is generally given at low doses (100–200 mg per day) to inhibit P450 and boost the co-administered protease inhibitors. Most protease inhibitors are associated with hyperlipidaemia and other metabolic abnormalities such as insulin resistance. Long-term protease inhibitor exposure has been associated with increased risk of cardiovascular disease
CCR5 inhibitors	Maraviroc	Maraviroc is only active in patients who do not have virions that use CXCR4 for cell entry. A specialised assay is therefore needed to screen for co-receptor tropism. By contrast with other antiretroviral drugs, maraviroc binds to a host rather than a viral target. Maraviroc has an immunomodulatory effect that is independent of its effect on HIV replication; the clinical significance of this activity is unknown
Fusion inhibitors	Enfuvirtide	Enfuvirtide must be given subcutaneously twice daily and is very expensive. The drug is generally used only in patients with no other therapeutic options
^a Some drugs such as zidovudine, stavudine, and nevirapine are generally used in resource-limited regions because of cost considerations. These drugs are generally not recommended as preferred agents in resource-rich regions in view of their potential toxic effects. (From: Volberding PA, Deeks SG. Antiretroviral therapy and management of HIV infection. <i>Lancet</i> 2010; 376:496–472.)		

and enzymes. As a consequence, viral maturation is impaired and immature dysfunctional viral particles are produced. Most of the protease inhibitors are active at very low concentrations and *in vitro* are found to have synergy with reverse transcriptase inhibitors. However, there are differences in toxicity, pharmacokinetics, resistance patterns and also cost, which influence prescribing. Cross-resistance can occur across the PI group. There appears to be no activity against human aspartyl proteases (e.g. renin), although there are clinically significant interactions with the cytochrome P450 system. This is used to therapeutic advantage, 'boosting' blood levels of PI by blocking drug breakdown with small doses of ritonavir. PIs have been linked with abnormalities of fat metabolism and control of blood sugar and some have been associated with deterioration in clotting function in people with haemophilia. Second generation PIs (e.g. darunavir, tipranavir) with activity against viruses resistant to the first generation drugs are available.

Integrase inhibitors

These drugs act as a selective inhibitor of HIV integrase, which blocks viral replication by preventing insertion of HIV DNA into the human DNA genome. Three compounds have so far been developed, although only one, raltegravir, is used. Raltegravir is metabolized by glucuronidation and does not

require retroviral drug boosting. It is effective in treatment of both experienced and naive patients.

Co-receptor blockers

Maraviroc is a chemokine receptor antagonist which blocks the cellular CCR5 receptor entry by CCR5 tropic strains of HIV. These strains are found in earlier HIV infection and, with time adaptations (against which maraviroc is ineffective) allow the CXCR4 receptor to become the more dominant form. The drug is metabolized by CYP p450 (3A), giving the potential for drug–drug interactions. Tropism assays to establish that the patient is carrying a CCR5 tropic virus are required before treatment is used.

Fusion inhibitors

Enfuvirtide is the only licensed compound in this class of agents. It is an injectable peptide derived from HIV gp41 that inhibits gp41-mediated fusion of HIV with the target cell. It is synergistic with NRTIs and PIs. Although resistance to enfuvirtide has been described, there is no evidence of cross-resistance with other drug classes. Because it has an extracellular mode of action there are few drug–drug interactions. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.

Box 4.26 Prescribing antiretroviral drugs: practice points

Characteristics of antiretroviral agents	Practice points
Must be taken exactly as prescribed	Check for any factors that may compromise accurate adherence Ensure that the proposed drug regimen fits with lifestyles Clarify that the patient is fully conversant with the requirements and understands the reasons for strict adherence Check access to appropriate storage conditions for some agents
Should not be stopped suddenly	Make sure that mechanisms are in place to ensure adequate drug supplies, e.g. regular clinic appointments, repeat prescriptions, home delivery of medications Beware unexpected time away from home, e.g. holidays, intercurrent hospital admissions, immigration detention, police detention If there is an urgent medical indication to stop, obtain advice from specialist physician or pharmacist
Can be compromised by the introduction of other medications, including other ARVs and vice versa	Be careful with enzyme inducers, e.g. rifampicin, rifabutin, warfarin, nevirapine, which will reduce the effective levels of some ARVs Methadone levels may be reduced by efavirenz Some ARVs block the metabolism of other agents which may reach toxic levels Check potential interactions before adding new agents, see: www.hiv-druginteractions.org Therapeutic drug monitoring is necessary
Can adversely interact with some herbal, complementary and recreational agents	Herbal remedies that induce cytochrome P450, e.g. St John's wort; Chinese herbal remedies will reduce levels of some ARVs Check potential interactions before adding new agents, see: www.hiv-druginteractions.org Therapeutic drug monitoring is necessary
May produce additive toxicities when given with other medications	E.g. hepatotoxicity with antituberculosis medication, myelosuppression with chemotherapy or high-dose co-trimoxazole
Are associated with a range of adverse drug reactions which may be confused with other pathology	For example, rash, fever, nausea, diarrhoea may all be caused by intercurrent pathology and/or ARVs
May exacerbate co-morbidities	Immune reconstitution inflammatory syndrome (IRIS). Examples include hepatic dysfunction due to hepatitis B and C, cardiovascular risk, osteoporosis

Starting therapy

Although the benefits of HAART in HIV infection are now indisputable, treatment regimens require a long-term commitment to high levels of adherence. Risks of therapy include short- and longer-term side-effects, drug–drug interactions and the potential for development of resistant viral strains. The full involvement of patients in therapeutic decision-making is essential for success. Various national guidelines and treatment frameworks exist (e.g. BHIVA Guidelines, DHHS Guidelines and IAS Recommendations). Laboratory marker data, including viral load and CD4 counts, together with individual circumstances, should guide therapeutic decision-making. The current UK recommendations are shown in Table 4.54. In situations where therapy is recommended but the patient elects not to start, then more intensive clinical and laboratory monitoring is advisable.

Questions still remain about the best time to start therapy. Clear clinical benefit has been demonstrated with the use of antiretroviral drugs in advanced HIV disease. All patients with symptomatic HIV disease, AIDS or a CD4 count that is consistently below 200 cells/mm³ should initiate treatment as soon as possible. In such situations, there is a significant risk of serious HIV-associated morbidity and mortality and the longer-term prognosis for patients initiating therapy below 200 CD4 cells/mm³ is not as good as for those who start at higher counts.

In asymptomatic patients, the absolute CD4 count is the key investigation used to guide treatment decisions. The UK recommendation is that therapy should be started at or around a CD4 count of 350 and patients with CD4 counts between 200 and 350 cells/mm³ should start therapy as soon as they are ready.

Debate remains about starting therapy at higher CD4 counts. The risk of disease progression for individuals with a count >350 is low and has to be balanced against ARV therapy toxicity and development of resistance. Earlier intervention at higher CD4 counts may be considered in those with a higher risk of disease progression, e.g. with high viral loads (>60 000 copies/mL) or rapidly falling CD4 count (losing more than 80 cells/year). Co-infection with hepatitis C virus is also a factor for earlier intervention (see p. 324).

Treatment for primary HIV infection is only recommended either within a clinical trial or to alleviate symptoms. Special situations (seroconversion, pregnancy, post-exposure prophylaxis) in which antiretroviral agents may be used are described on page 186.

Choice of drugs

The drug regimen used for starting therapy must be individualized to suit each patient's needs. As differences in drug efficacy become less marked, fitting the drugs to the patient's needs and lifestyle are key to success. Treatment is initiated with three drugs, two NRTIs in combination, with either an NNRTI or a boosted protease inhibitor (Table 4.53 and Table 4.55). The development of fixed-dose coformulations reduces pill burden, increases convenience and facilitates adherence. Newer drug classes such as integrase inhibitors and regimens without an NRTI backbone are still in the trial process and are likely to be the next development in first-line therapy.

Nucleoside reverse transcriptase inhibitor (NRTI)

Which two NRTIs form the backbone is influenced by efficacy, toxicity and ease of administration. The availability of once daily one-tablet fixed-dose combinations, *Truvada*

(TDF/FTC) and *Kivexa* (ABC/3TC), has led to the majority of patients who are naive to medication being prescribed one of these as their 2NRTI backbone. *Kivexa* should only be used in those who are HLAB*5701 negative. *Combivir* (ZDV/3TC) has lower efficacy than *Truvada*, a twice-daily dosing schedule and poorer toxicity profile. Data comparing *Truvada* and *Kivexa* in naive patients has demonstrated non-inferiority of *Kivexa* at viral levels below 100 000 copies/mL and there is concern over an association of abacavir with cardiovascular events. In patients with high viral levels *Kivexa* should be reserved for use when *Truvada* is contraindicated. *Stavudine* is associated with lipodystrophy and peripheral neuropathy and is no longer used as first-line therapy in the UK, although it continues to be used widely in other parts of the world.

Non-nucleoside reverse transcriptase inhibitor (NNRTI)

The decision about use of NNRTI or boosted PI will depend on the particular circumstances of each patient but in the UK, an NNRTI-based regimen is most commonly prescribed to naive patients.

Efavirenz is the recommended option in the UK, having demonstrated good durability over time, potency at low CD4

counts and in high viral loads. Efavirenz has the advantage of once-daily dosing but is associated with CNS side-effects such as dysphoria and insomnia and is contraindicated in pregnancy. The fixed-dose preparation of efavirenz co-formulated with *Truvada* (Atripla) allows for a 'one pill once a day' regimen.

Nevirapine is of equivalent potency to efavirenz but has a higher incidence of hepatotoxicity and rash. Toxicity is greater in women and in those with higher CD4 counts. It is contraindicated in women with CD4 counts above 250 cells and in men with counts above 400. It can be a useful alternative to efavirenz if CNS side-effects are troublesome and in women with lower CD4 counts who wish to conceive.

Etravirine and rilpivirine are second generation NNRTIs, active against drug-resistant strains and useful in treatment of experienced patients.

Protease inhibitors

This class of drugs has demonstrated excellent efficacy in clinical practice. PIs are usually combined with a low dose of ritonavir (a 'boosting' PI), which provides a pharmacokinetic advantage by blocking cytochrome P450 metabolism. Using this approach, the half-life of the active drug is increased, allowing greater drug exposure, fewer pills, enhanced potency and the risk of resistance minimized. The disadvantages include a greater pill burden and increased risk of greater lipid abnormalities, particularly raised fasting triglycerides. Cobicistat, a novel cytochrome P450 inhibitor with no intrinsic anti-HIV activity, is in clinical trials.

Atazanavir, darunavir or lopinavir, boosted with ritonavir, are most commonly used as first-line therapy. All three can cause GI disturbance and lipid abnormalities. Atazanavir increases unconjugated bilirubin levels and may produce icterus. All have interactions with cytochrome P450.

Monitoring therapy (Box 4.27)

Success rates for initial therapy using modern ARVs judged by virological response are very high. By 4 weeks of therapy, the viral load should have dropped by at least 1 log₁₀ copies/mL and by 12–24 weeks should be below 50 copies/mL. A suboptimal response at either time point demands a full assessment and possible change in therapy.

Table 4.54 When to start antiretroviral therapy

Primary HIV infection	Treatment in clinical trial or if there is neurological involvement or if the CD4 <200 for >3/12 or if an AIDS-defining illness is present
Established HIV infection	
CD4 <250	Treat
CD4 251–350	Treat as soon as patient ready
CD4 >350	Consider enrolment into 'when to start' trial
AIDS diagnosis/CDC stage C	Treat (except for TB when CD4 >350)
Modified from Williams I, et al. British HIV Association guidelines for the treatment of HIV-1-positive adults with antiretroviral therapy 2012.	

Table 4.55 Initial HAART regimens – choice of initial therapy. Preferred regimens

Therapy naïve patients should start with a regimen that contains two NRTIs and a third agent, either a ritonavir-boosted protease inhibitor, or a NNRTI or an integrase inhibitor		
	Preferred	Alternative
NRTI	Tenofovir [†] Emtricitabine [†]	Abacavir ^{§1} Lamivudine [§]
Third agent	Atazanavir/ritonavir Darunavir/ritonavir Efavirenz Raltegravir	Lopinavir/ritonavir Fosamprenavir/ritonavir Nevirapine ² Rilpivirine ³
Drugs listed in alphabetical order [†] co formulated as <i>Truvada</i> [§] co-formulated as <i>Kivexa</i> 1. Abacavir is contraindicated if HLA B*5701 positive 2. Nevirapine is contra-indicated if baseline CD4 greater than 250 cells/μL in women or greater than 400 cells/μL in men 3. Use recommended only if baseline viral load less than 100,000 copies/mL Modified from Williams, I et al. British HIV Association guidelines for the treatment of HIV-1-positive adults with antiretroviral therapy 2012. April 2012 http://www.bhiva.org/TreatmentofHIV1_2012.aspx		

Box 4.27 Monitoring patients on highly active antiretroviral therapy (HAART)

Clinical history including:

- Assessment of adherence to medication
- Evidence of antiretroviral therapy (ART) toxicity

Physical examination:

- Blood pressure
- Weight
- HIV viral load
- Lymphocyte subsets
- Full blood count
- Urinalysis if taking tenofovir
- Liver and renal function
- Fasting lipid profile
- Fasting blood glucose

Additional investigations (depending on the clinical picture) may include:

- HIV genotype if there is evidence of virological failure
- Therapeutic drug level monitoring

Once stable on therapy the viral load should be routinely measured every 3–4 months. CD4 count should be repeated at 1 and 3 months after starting HAART and then every 3–4 months. Once both the viral load is below 50 copies/mL and the CD4 count has been above 350 cells for at least 12 months frequency may fall to 6 monthly. Impaired immunological recovery is associated with treatment initiation in advanced infection (a low CD 4 count and late presentation) and with older age.

Regular clinical assessment should include review of adherence to and tolerability of the regimen, weight, blood pressure and urinalysis. Patients should be monitored for drug toxicity, including full blood count, liver and renal function and fasting lipids and glucose levels.

Drug resistance

Resistance to ARVs (Box 4.28) results from mutations in the protease reverse transcriptase and integrase genes of the virus. HIV has a rapid turnover with 10^8 replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual, which will include drug-resistant mutants. When drugs only partially inhibit virus replication there will be a selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the frequency of pre-existing variants and the number of mutations required. Resistance to most NRTIs and PIs occurs with an accumulation of mutations, whilst a single point mutation will confer high-level resistance to NNRTIs. There is evidence for the transmission of HIV strains that are resistant to all or some classes of drugs. Studies of primary HIV infection have shown prevalence rates between 2% and 20%. Prevalence of primary mutations associated with drug resistance in chronically infected patients not on treatment ranges from 3% to 10% in various studies.

HIV antiretroviral drug resistance testing has become routine clinical management in patients at diagnosis/before starting therapy and for whom therapy is failing. The tests are based on PCR amplification of virus and give an indirect measure of drug susceptibility in the predominant variants. Such assays are limited both by the starting concentration of virus and their ability to detect minority strains.

For results to be useful in situations where therapy is failing, samples must be analysed when the patient is on

Box 4.28 Mechanisms and implications of HIV drug resistance

1. HIV replicates rapidly and inaccurately. Replication in the presence of antiretroviral drugs leads to a selection pressure for those mutations which can survive, i.e. selects for drug resistance
2. Specific point mutations in the viral reverse transcriptase, protease and integrase genes correlate with reduced drug sensitivity and can be identified by genotyping the virus
3. Inadequate antiretroviral (ARV) drug levels both fail to suppress viral replication/viral load and precipitate drug resistance
4. Inadequate drug levels can result from poor adherence, altered GI tract absorption, increased drug breakdown and drug-drug interactions
5. Some ARVs, especially NNRTIs, have a low genetic barrier, i.e. a small number of mutations that occur rapidly can quickly result in high levels of resistance
6. Stopping drugs with a long half-life can leave a subtherapeutic drug tail for long enough for resistant strains to develop
7. In patients on stable ARV therapy, the introduction of new drugs that have an impact on cytochrome P450 pathways can lead to dangerous alterations in ARV drug levels
8. Therapeutic drug monitoring (TDM) may be a useful investigation for some drugs in some circumstances
9. Without drug selection pressure wild type virus reasserts itself and resistant variants no longer make up the major circulating viral strains and may not be found on investigation. This means that genotyping should if possible be carried out on specimens obtained whilst on therapy
10. Resistant variants survive and are archived. They reappear if the drug selection pressure is reintroduced. This means that all previous genotypes need to be considered when assessing virological failure and planning new therapy

therapy, as once the selection pressure of therapy is withdrawn, wild type virus becomes the predominant strain and resistance mutations present earlier may no longer be detectable.

Databases containing nearly all published HIV (amongst others) and protease sequences and associated resistance patterns are maintained in real time by Stanford University (see: <http://hivdb.stanford.edu>).

Phenotypic assays provide a more direct measure of susceptibility but the complexity of the assays limits availability.

Drug interactions

Drug therapy in HIV is complex and the potential for clinically relevant drug interactions is substantial. Both PIs and NNRTIs are able to variably inhibit and induce cytochrome P450, influencing both their own and other drug metabolic rates. Both inducers and inhibitors of cytochrome P450 are sometimes prescribed simultaneously. Induction of metabolism may result in subtherapeutic antiretroviral drug levels with the risk of treatment failure and development of viral resistance, whilst inhibition can raise drug levels to toxic values and precipitate adverse reactions.

Conventional (e.g. rifamycins) and complementary therapies (e.g. St John's wort) affect cytochrome P450 activity and may precipitate substantial drug interactions. Therapeutic drug monitoring (TDM) indicating peak and trough plasma levels may be useful in certain settings.

Potential interactions can be checked using the online tool maintained by Liverpool University at www.hiv-druginteractions.org.

Wainberg MA et al. Development of antiretroviral drug resistance. *N Engl J Med* 2011; 365:637–646.

Adherence

Patients' beliefs about their personal need for medicines and their concerns about treatment affect how and whether they take them. Adherence to treatment is pivotal to success. Levels of adherence below 95% have been associated with poor virological and immunological responses although some of the newer ARVs are more forgiving. Poor absorption and low bioavailability mean that for some compounds trough levels are barely adequate to suppress viral replication and missing even a single dose will result in plasma drug levels falling dangerously low. Patchy adherence facilitates the emergence of drug-resistant variants, which in time will lead to virological treatment failure.

Factors implicated in poor adherence may be associated with the medication, with the patient or with the provider. The former include side-effects associated with medications, the degree of complexity and pill burden and inconvenience of the regimen. Patient factors include the level of motivation and commitment to the therapy, psychological wellbeing, the level of available family and social support and health beliefs. Supporting adherence is a key part of clinical care and specific guidelines are available (BHIVA 2004). Education of patients about their condition and treatment is a fundamental requirement for good adherence, as is education of clinicians in adherence support techniques. The acceptability and tolerability of the regimen together with an assessment of adherence should be documented at each visit. Provision of acute and ongoing multidisciplinary support for adherence within clinical settings should be universal. Medication-alert devices may be useful for some patients.

Treatment failure

Failure of antiretroviral treatment, i.e. persistent viral replication causing immunological deterioration and eventual clinical evidence of disease progression, is caused by a variety of factors, e.g. poor adherence, limited drug potency and food or other medication may compromise drug absorption. There may be drug interactions or limited penetration of drug into sanctuary sites such as the CNS, permitting viral replication. Side-effects and other patient-related elements contribute to poor adherence.

Changing therapy

A rise in viral load, a falling CD4 count or new clinical events that imply progression of HIV disease are all reasons to review therapy. Reasons for treatment failure include the emergence of resistant viral strains, poor patient adherence or intolerance/adverse drug reactions. Virological failure, i.e. two consecutive viral loads of >400 copies/mL in a previously fully suppressed patient, requires investigation. Viral genotyping should be used to help select future therapy, choosing at least two new agents to which the virus is fully sensitive. If a new suitable treatment option is available it should be started as soon as possible.

Treatment failure in highly treatment-experienced patients poses considerable challenges, but new classes of antiretroviral agents, with activity against drug-resistant strains of HIV, make long-term virological suppression a realistic objective, even in heavily pre-treated patients. However, in some situations it may be better to hold back a new drug and await development of another new agent to give the maximum chance of success.

If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance of a particular drug, then a switch to another sensitive drug within

the same class should be made. Simplification of complex regimens may be considered if adherence is problematic.

Stopping therapy

Antiretroviral drugs may have to be stopped in, for example, cumulative toxicity, or potential drug interactions with medications needed to deal with another more pressing problem. If adherence is poor, stopping completely may be preferable to continuing with inadequate dosing, in order to reduce the development of viral resistance. Poor quality of life and the view of the patient should be discussed.

NNRTIs efavirenz and nevirapine have long half-lives and therefore should be stopped *before* the other drugs in the mixture to reduce the risk of drug resistance. If this is not possible, lopinavir/ritonavir may be used either in substitution of the NNRTI or as monotherapy for several weeks to cover the period of subtherapeutic levels.

Data from a large international trial, the SMART study, on intermittent antiretroviral therapy (even with CD4 counts above 250 cells/mL) suggests these patients do less well than those on continuous therapy. Current British guidance does not support treatment interruption as a standard of care.

Complications of antiretroviral therapy

Side-effects are a common problem in HAART (see Table 4.53). Some are acute and associated with initiation of medication, whilst others emerge after longer-term exposure to drugs.

Allergic reactions

Allergic reactions occur with greater frequency in HIV infection and have been documented with all the antiretroviral drugs. Abacavir is associated with a potentially fatal hypersensitivity reaction, strongly associated with the presence of HLAB*5701, usually within the first 6 weeks of treatment. There may be a discrete rash and often a fever coupled with general malaise and gastrointestinal and respiratory symptoms. The diagnosis is clinical and symptoms resolve when abacavir is withdrawn. Re-challenge with abacavir can be fatal and is contraindicated. In the UK routine screening for the HLAB*5701 allele has reduced the incidence of abacavir hypersensitivity. Allergies to NNRTIs (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver biochemical tests. Reactions can resolve even with continuing therapy but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

Lipodystrophy and metabolic syndrome

A syndrome of lipodystrophy occurs in patients with HIV on HAART comprising characteristic morphological changes and metabolic abnormalities. The main characteristics include a loss of subcutaneous fat in the arms, legs and face (lipoatrophy), deposition of visceral, breast and local fat, raised total cholesterol, HDL cholesterol and triglycerides and insulin resistance with hyperglycaemia. The syndrome is potentially associated with increased cardiovascular morbidity. The aetiology is unclear, although PIs and NRTIs have been implicated. The highest incidence occurs in those taking combinations of NRTIs and PIs. Stavudine and zidovudine are associated with the lipoatrophy component of the process. Dietary advice and increasing exercise may improve some of the metabolic problems and help body shape. Statins and fibrates are recommended to reduce circulating lipids. In 2010, the US FDA approved tesamorelin to help

treat HIV patients with lipodystrophy. Simvastatin is contraindicated as it has high levels of drug interactions with PIs.

Mitochondrial toxicity and lactic acidosis

Mitochondrial toxicity, mostly involving the older drugs stavudine and didanosine in nucleoside analogue class, leads to raised lactate and lactic acidosis, which has in some cases been fatal. NRTIs inhibit gamma DNA polymerase and other enzymes that are necessary for normal mitochondrial function. Symptoms are often vague and insidious and include anorexia, nausea, abdominal pain and general malaise. Venous lactate is raised and the anion gap is typically widened. This is a serious condition requiring immediate cessation of antiretroviral therapy and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to possible symptoms and encouraged to attend hospital promptly.

Bone metabolism

A variety of bone disorders have been reported in HIV, in particular osteopenia, osteoporosis and avascular necrosis. The prevalence of these conditions has varied widely in different studies. Antiretroviral agents, particularly PIs, have been implicated in the aetiology, although untreated HIV is believed to have a direct impact on bone metabolism.

IRIS

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) may occur on initiating HAART. This occurs usually in people who have been profoundly immunosuppressed and begin therapy. As their immune system recovers, they are able to mount an inflammatory response to a range of pathogens, which can include exacerbation of symptoms with new or worsening of clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, including deteriorating radiological appearances associated with TB infection. Inflammatory retinal lesions in association with cytomegalovirus, deterioration in liver function in chronic hepatitis B carriers and vigorous vesicular eruptions with herpes zoster have also been described.

Specific therapeutic situations

Acute seroconversion

Antiretroviral therapy in patients presenting with an acute seroconversion illness is controversial. This stage of disease may represent a unique opportunity for therapy as there is less viral diversity and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by aggressive therapy at this stage, although it rises when treatment is withdrawn. The longer-term clinical sequelae of treatment at this stage remain uncertain. People with severe symptoms during primary HIV infection may gain a clinical improvement on antiretrovirals. If treatment is contemplated in this situation, entry into a clinical trial is sensible.

Pregnancy

In the UK, the mother-to-child HIV transmission rate is 1% for all women diagnosed prior to delivery and 0.1% for women on HAART with a viral load below 50 copies/mL. Management of HIV-positive pregnant women requires close collaboration between obstetric, medical and paediatric teams. The management aim is to deliver a healthy, uninfected baby to a healthy mother without prejudicing the future treatment options of the mother. Although

considerations of pregnancy must be factored into clinical decision-making, pregnancy *per se* should not be a contraindication to providing optimum HIV-related care for the woman. HIV-positive women are advised against breastfeeding, which doubles the risk of vertical transmission. Delivery by caesarean section reduced the risk of vertical transmission in the pre HAART era but if the woman is on effective HAART and the labour is uncomplicated vaginal delivery carries no additional risk. For women eligible for treatment of their own HIV disease, whether pregnant or not, triple therapy is the regimen of choice. Risk of vertical transmission increases with viral load. Although the fetus will be exposed to more drugs, the chances of reducing the viral load and hence preventing infection are greatest with a potent triple therapy regimen in the mother.

Treatment should start as soon as possible and continue during delivery. The baby should receive zidovudine for 4 weeks postpartum and the mother remain on ARVs with appropriate monitoring and support.

Women who do not need treatment for themselves should be prescribed a short course of antiretroviral therapy initiated at approximately 20 weeks of pregnancy to reduce vertical transmission. Efavirenz has been associated with developmental abnormalities in primate models and several retrospective cases of neural tube defects in babies born to women taking efavirenz have been reported. Women who have conceived on the drug should discuss the risks and benefits of continuing or switching with an expert clinician.

Details of adverse effects associated with ARVs in pregnancy are maintained by the antiretroviral pregnancy registry, which holds prospective international data and is regularly updated (see: www.apregistry.com).

Post-exposure prophylaxis

The time taken for HIV infection to become established after exposure offers an opportunity for prevention. Animal models provide support for the use of triple ARVs for post-exposure prophylaxis (PEP) but there are no prospective trials to inform the best approach and each situation should be evaluated on a case by case basis to estimate the potential risk of infection and potential treatment benefit. Healthcare workers may be treated following occupational exposure to HIV as may those exposed sexually. The risk of acquisition of HIV following exposure is dependent upon the risk that the source is HIV positive (if this is unknown in a sexual exposure) and the risk of transmission of the particular exposure. PEP may be useful up to 72 hours after possible exposure. In the UK, the standard regimen is Truvada plus Kaletra although this may be varied depending on what is known about the source. Treatment is given for 4 weeks and the recipient should be monitored for toxicity. The at-risk patient should be tested for established HIV infection before PEP is dispensed. Rapid point-of-care tests are particularly useful in this setting. PEP following sexual exposure should not be seen as a substitute for other methods of prevention. Pre-exposure prophylaxis is discussed on [page 193](#).

Opportunistic infections in the HAART era

Although effective antiretroviral therapy has resulted in a remarkable decline in opportunistic infections in patients with HIV, not all those at risk may be either on or adhering to effective treatment. In 2009, 19% of those newly diagnosed with HIV in the UK had a CD4 count below 200 cells/ μ L at presentation and over 25% of those living with HIV remain

FURTHER READING

Costello DJ, Gonzalez G, Frosch MP. Case 18–2011 – A 35-year-old HIV-positive woman with headache and altered mental status. *N Engl J Med* 2011; 364:2343–2352.

undiagnosed, making late presentation and OI more likely. In parallel, the types of infections seen in the context of HIV have altered with fewer episodes of the 'classic' OIs, such as pneumocystis pneumonia and cytomegalovirus, but an increase in community-acquired infections such as *Strep. pneumoniae* and *Haemophilus influenzae* (Table 4.56).

Immune reconstitution with HAART may produce unusual responses to opportunistic pathogens and confuse the

clinical picture. Thus prevention and treatment of OIs remains an integral part of the management of HIV infection.

Prevention of opportunistic infection in HIV-infected patients

Avoid infection

Exposure to certain organisms can be avoided in those known to be HIV-infected. Attention to food hygiene will

Table 4.56 Some causes of opportunistic pneumonia in immunocompromised patients (see Table 15.16)

Pathogen	Affected patient population	Clinical and radiographic features
<i>Pneumocystis jiroveci</i>	Impaired cell-mediated immunity: HIV infection with CD4 <200/mm ³ , long-term corticosteroid use, immunosuppressant drugs	<i>Pneumocystis</i> pneumonia Perihilar ground-glass shadowing, cysts
Non-tuberculous mycobacterial species	Impaired cell-mediated immunity: HIV infection CD4 usually <200/mm ³ Structural lung disease: bronchiectasis, cystic fibrosis, severe COPD	Varied clinical presentation (see p. 736): Nonspecific fevers, cough, malaise Lymphadenopathy or hepatosplenomegaly <i>CT findings</i> : nodules, cavitation, thickened airways, 'tree-in-bud' small airways
<i>Nocardia</i> spp.	Impaired cell-mediated immunity: HIV infection CD4 usually <150/mm ³ , chronic corticosteroid use, post-solid-organ transplantation, post stem cell transplantation Structural lung disease: bronchiectasis, cystic fibrosis, severe COPD	Acute, sub-acute or chronic pneumonia <i>Multiple radiographic presentations</i> include lobar infiltrates, abscesses, cavities, pleural effusion, pulmonary nodules
<i>Aspergillus</i> spp. <i>Zygomycetes</i> spp. <i>Penicillium</i> spp.	Prolonged neutropenia: post-chemotherapy for haematological malignancy, post-stem cell transplant (myeloablative transplants are at particular risk) Impaired cell-mediated immunity: graft-versus-host disease, immunosuppressant therapy Chronic granulomatous disease	Invasive fungal pneumonia characterized by cough ± haemoptysis, pleuritic pain and fevers <i>CT findings</i> are any of: cavitating consolidation, 'tree-in-bud', nodules with ground glass halo and in later stages air-crescent sign (caused by lung necrosis)
<i>Cryptococcus</i> spp.	Impaired cell-mediated immunity: HIV infection CD4 usually <200/mm ³ , chronic corticosteroid use, post-solid-organ transplantation, post-stem cell transplantation	Nonspecific respiratory symptoms of fever, cough, breathlessness Usually associated with neurological involvement isolated pulmonary disease does occur Progresses to disseminated disease in immunocompromised patients <i>CT findings</i> are any of: cavities, nodules, infiltrates
<i>Histoplasma capsulatum</i>	Impaired cell-mediated immunity: HIV infection CD4 usually <50/mm ³	Fever, fatigue, weight loss Cough and dyspnoea are the most common respiratory symptoms <i>Chest X-ray</i> can be normal in disseminated disease <i>CT findings</i> : diffuse reticular/reticulonodular infiltrates, miliary infiltrates, occasionally mediastinal lymphadenopathy
Coccidioidomycosis Paracoccidioidomycosis Blastomycosis	Impaired cell-mediated immunity: HIV infection CD4 usually <50/mm ³	Often presents as disseminated disease (chest X-ray often normal) Focal or diffuse pneumonia <i>CT findings</i> : diffuse reticulonodular infiltrates, consolidation, nodules (multiple or single), cavities, mediastinal lymphadenopathy
Cytomegalovirus (Uncommon – usually presents with retinitis or colitis)	Impaired cell-mediated immunity: HIV infection CD4 usually <50/mm ³ , post-transplantation on immunosuppressant therapy	Cough, dyspnoea and fever <i>CT findings</i> : reticular or ground-glass opacities, alveolar infiltrates, nodules/nodular opacities, pleural effusions
Respiratory syncytial virus, Human metapneumovirus, influenza, parainfluenza	Impaired cell-mediated immunity: HIV infection CD4 usually <200/mm ³ , chronic corticosteroid use, post-solid-organ transplantation, post-stem cell transplantation	Cough, dyspnoea and fever <i>CT findings</i> : ground glass opacification, air-space shadowing, 'tree-in-bud', airway dilatation and wall thickening
<i>Toxoplasma gondii</i>	Impaired cell-mediated immunity: HIV infection CD4 usually <100/mm ³	Isolated pulmonary or disseminated disease Dry cough, fever, dyspnoea <i>CT findings</i> : appearance similar to PCP or fungal pneumonia; pleural effusion

Box 4.29 Use of vaccines in HIV-infected adults

Vaccines that can be used in all HIV-infected adults (all inactivated)	Vaccines that are contraindicated in all HIV-infected adults	Vaccines that can be used only in asymptomatic HIV-infected adults with a current CD4 count >200 cells/mm ³

Based on BHIVA Guidelines 2006: www.bhiva.org.

reduce exposure to *Salmonella*, toxoplasmosis and *Cryptosporidium* and protected sexual intercourse will reduce exposure to herpes simplex virus (HSV), hepatitis B and C and papillomaviruses. Cytomegalovirus (CMV)-negative patients should be given CMV-negative blood products. Travel-related infection can be minimized with appropriate advice.

Immunization strategies (Box 4.29)

Guidance on the appropriate use of vaccines in HIV is available from: www.bhiva.org/files. Immunization may not be as effective in HIV-infected individuals.

Hepatitis A and B vaccines should be given for those without natural immunity who are at risk, particularly if there is co-existing liver pathology, e.g. hepatitis C.

Chemoprophylaxis

In the absence of a normal immune response, many OIs are hard to eradicate using antimicrobials and the recurrence rate is high. Primary and secondary chemoprophylaxis has reduced the incidence of many OIs. Advantages must be balanced against the potential for toxicity, drug interactions and cost, with each medication added to what are often complex drug regimens.

- Primary prophylaxis is effective in reducing the risk of *Pneumocystis jiroveci*, toxoplasmosis and *Mycobacterium avium-intracellulare*.
- Primary prophylaxis is **not** normally recommended against cytomegalovirus, herpesviruses or fungi.

With the introduction of HAART and immune reconstitution, ongoing chemoprophylaxis can be discontinued in those patients with CD4 counts that remain consistently above 200. In areas where effective HAART may not be available, long-term secondary prophylaxis still has a role. Other less severe but recurrent infections may also warrant prophylaxis (e.g. herpes simplex, candidiasis).

Specific conditions associated with HIV infection

Fungal infections

Pneumocystis jiroveci (see p. 839)

This organism most commonly causes pneumonia (PCP) but can cause disseminated infection. It is not usually seen until

patients are severely immunocompromised with a CD4 count below 200. The introduction of effective antiretroviral therapy and primary prophylaxis in patients with CD4 <200 has significantly reduced the incidence in the UK. The organism damages alveolar epithelium, which impedes gas exchange and reduces lung compliance.

The onset is often insidious over a period of weeks, with a prolonged period of increasing shortness of breath (usually on exertion), non-productive cough, fever and malaise. *Clinical examination* reveals tachypnoea, tachycardia, cyanosis and signs of hypoxia. Fine crackles are heard on auscultation, although in mild cases there may be no auscultatory abnormality. In early infection the chest X-ray is normal but the typical appearances are of bilateral perihilar interstitial infiltrates, which can progress to confluent alveolar shadows throughout the lungs. High-resolution CT scans of the chest demonstrate a characteristic ground-glass appearance even when there is little to see on the chest X-ray. The patient is usually hypoxic and desaturates on exercise. Definitive diagnosis rests on demonstrating the organisms in the lungs via bronchoalveolar lavage or by PCR amplification of the fungal DNA from a peripheral blood sample. As the organism cannot be cultured *in vitro* it must be directly observed either with silver staining or immunofluorescent techniques.

Treatment should be instituted as early as possible. First-line therapy is with intravenous co-trimoxazole (120 mg/kg daily in divided doses) for 21 days. Up to 40% of patients receiving this regimen will develop some adverse drug reaction, including a typical allergic rash. If the patient is sensitive to co-trimoxazole, intravenous pentamidine (4 mg/kg per day) or dapsone and trimethoprim are given for the same duration. Atovaquone or a combination of clindamycin and primaquine is also used. In severe cases (P_{aO_2} <9.5 kPa), systemic corticosteroids reduce mortality and should be added. Continuous positive airways pressure (CPAP) or mechanical ventilation (see p. 894) is required if the patient remains severely hypoxic or becomes too tired. Pneumothorax may complicate the clinical course in an already severely hypoxic patient. If not already on antiretroviral therapy, HAART should be initiated early in the course of infection.

Secondary prophylaxis is required in patients whose CD4 count remains below 200, to prevent relapse, the usual regimen being co-trimoxazole 960 mg three times a week. Patients sensitive to sulphonamide are given dapsone, pyrimethamine or nebulized pentamidine. The last only protects the lungs and does not penetrate the upper lobes

particularly efficiently; hence if relapses occur on this regimen they may be either atypical or extrapulmonary.

Cryptococcus

The most common presentation of cryptococcus infection (see p. 141) in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism, *C. neoformans*, is widely distributed – often in bird droppings – and is usually acquired by inhalation. The onset may be insidious with nonspecific fever, nausea and headache. As the infection progresses the conscious level is impaired and changes in affect may be noted. Fits or focal neurological presentations are uncommon. Neck stiffness and photophobia may be absent as these signs depend on the inflammatory response of the host, which in this setting is abnormal.

Diagnosis is made on examination of the CSF (perform CT scan before lumbar puncture to exclude space-occupying pathology). Indian ink staining shows the organisms directly and CSF cryptococcal antigen is positive at variable titre. It is unusual for the cryptococcal antigen to become negative after treatment, although the levels should fall substantially. Cryptococci can also be cultured from CSF and/or blood.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white cell count in the CSF and an impaired consciousness level at presentation.

Treatment. Initial treatment is usually with intravenous liposomal amphotericin B (4.0 mg/kg per day) \pm flucytosine as induction, although intravenous fluconazole (400 mg daily) is useful if renal function is impaired or if amphotericin side-effects are troublesome.

Patients diagnosed with cryptococcal disease should receive HAART, starting at approximately 2 weeks after commencement of cryptococcal treatment, to minimize the risk of IRIS.

Candida

Mucosal infection, particularly oral, with *Candida* (see p. 139) is common in HIV-infected patients. *C. albicans* is the usual organism, although *C. krusei* and *C. glabrata* occur. Pseudomembranous candidiasis consisting of creamy plaques in the mouth and pharynx is easily recognized but *erythematous Candida* appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form. Vulvovaginal *Candida* may be problematic.

Oesophageal Candida infection produces odynophagia (see p. 237). Fluconazole or itraconazole are the agents of choice. *Disseminated Candida* is uncommon in the context of HIV infection but if present, fluconazole is the preferred drug with amphotericin, voriconazole or caspofungin also used. *C. krusei* may colonize patients who have been treated with fluconazole, as it is fluconazole-resistant. Amphotericin is useful in the treatment of this infection and an attempt to type *Candida* from clinically azole-resistant patients should be made. The most successful strategy for managing HIV-positive patients with candidiasis is effective HAART.

Aspergillus

Infection with *Aspergillus fumigatus* (see p. 141) is rare in HIV, unless there are co-existing factors such as lung pathology, neutropenia, transplantation or glucocorticoid use. Spores are air-borne and ubiquitous. Following inhalation, lung infection proceeds to haematogenous spread to other organs. Sinus infection occurs.

Voriconazole is the preferred therapy with liposomal amphotericin B (3 mg/kg i.v. daily) as an alternative. Caspofungin is also effective.

Histoplasmosis, blastomycosis, coccidioidomycosis and penicillium marneffei

These fungal infections are geographically restricted but should be considered in HIV-positive patients who have travelled to areas of high risk. The most common manifestation is with pneumonia, which may be confused with *Pneumocystis jiroveci* in its presentation (see above), although systemic infection is reported, particularly with *Penicillium*, which can also produce papular skin lesions. Treatment is with amphotericin B.

Protozoal infections

Toxoplasmosis

Toxoplasma gondii (see p. 149) most commonly causes encephalitis and cerebral abscess in the context of HIV, usually as a result of reactivation of previously acquired infection. The incidence depends on the rate of seropositivity to toxoplasmosis in the particular population. High antibody levels are found in France (90% of the adult population). About 25% of the adult UK population is seropositive to toxoplasma.

Clinical presentation is of a focal neurological lesion with convulsions, fever, headache and possible confusion. Examination reveals focal neurological signs in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most but not all cases of *Toxoplasma* serology is positive. Typically, contrast-enhanced CT scan of the brain shows multiple ring-enhancing lesions. A single lesion on CT may be found to be one of several on MRI. A solitary lesion on MRI, however, makes a diagnosis of toxoplasmosis unlikely.

Diagnosis. Characteristic radiological findings on CT and MRI. Single photon emission computed tomography (SPECT) may also be helpful differentiating toxoplasma from primary CNS lymphoma. In most cases, an empirical trial of anti-toxoplasmosis therapy is instituted and if this leads to radiological improvement within 3 weeks this is considered diagnostic. The differential diagnosis includes cerebral lymphoma, tuberculoma or focal cryptococcal infection.

Treatment is with pyrimethamine for at least 6 weeks (loading dose 200 mg, then 50 mg daily) combined with sulfadiazine and folinic acid. Clindamycin and pyrimethamine may be used in patients allergic to sulphonamide.

HAART should be initiated as soon as the patient is clinically stable, approximately 2 weeks after acute treatment has begun to minimize the risk of IRIS.

Cryptosporidiosis

Cryptosporidium parvum (see p. 151) can cause a self-limiting acute diarrhoea in an immunocompetent individual. In HIV infection it can cause severe and progressive watery diarrhoea which may be associated with anorexia, abdominal pain, nausea and vomiting. In the era of HAART the infection is rare. Cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. It is also associated with sclerosing cholangitis (see p. 338). The cysts are seen on stool specimen microscopy using Kinyoun acid-fast stain and are readily identified in small bowel biopsy specimens. HAART is associated with complete resolution of infection following

restoration of immune function; otherwise treatment is largely supportive. Nitazoxanide may have some effect.

Microsporidiosis

Enterocytozoon bieneusi and *Septata intestinalis* are a cause of diarrhoea. Spores can be detected in stools using a tri-chrome or fluorescent stain that attaches to the chitin of the spore surface. HAART and immune restoration is the treatment of choice and can have a dramatic effect.

Leishmaniasis

Leishmaniasis (see p. 148) occurs in immunosuppressed HIV-infected individuals who have been in endemic areas, which include South America, tropical Africa and much of the Mediterranean. Symptoms are frequently nonspecific, with fever, malaise, diarrhoea and weight loss. Splenomegaly, anaemia and thrombocytopenia are significant findings. Amastigotes may be seen on bone marrow biopsy or from splenic aspirates. Serological tests exist for *Leishmania* but they are not reliable in this setting.

Treatment. Liposomal amphotericin is the drug of choice and HAART once the patient is stable. Relapse is common without HAART, in which case long-term secondary prophylaxis may be given.

Viral infections

Hepatitis B (HBV) and C (HCV) viruses

Because of the comparable routes of transmission of hepatitis viruses (see p. 323 and p. 318) and HIV, co-infection is common, particularly in MSM, drug users and those infected by blood products. A higher prevalence of hepatitis viruses is found in those with HIV infection than in the general population. With the striking improvement in prognosis in HIV since the introduction of HAART, morbidity and mortality of HBV and HCV co-infection has become increasingly significant with a greater mortality and more rapid development of liver cirrhosis than is seen in mono-infection. In co-infected patients the hepatotoxicity associated with certain antiretroviral agents may be potentiated. Advice on alcohol use should be given to all co-infected patients (see p. 323).

Hepatitis B infection does not appear to influence the natural history of HIV; however, in HIV co-infected patients, there is a significantly reduced rate of hepatitis B e antigen (HBeAg) clearance and the risk of developing chronic infection is increased. HBV reactivation and reinfection is also seen. Liver disease occurs most commonly in those with high HBV DNA levels indicative of continuing replication. In HBV infection, detection and quantification of HBV DNA acts as a marker of viral activity, while the significance of viral genotype is still uncertain. Liver biopsy is useful to obtain a histological staging of disease.

Treatment for HBV should be initiated in co-infected patients with evidence of fibrotic liver damage or active HBV replication. Treatments for HBV include agents with concomitant anti-HIV activity, including lamivudine, tenofovir and emtricitabine. These must be used within an effective anti-HIV regimen. Initiation of HAART may result in a flare of HBV resulting from the improved immune function. If not already immune patients should be given vaccine against hepatitis A.

Hepatitis C is associated with more rapid progression of HIV infection and the CD4 responses to HAART in co-infected patients may be blunted. Hepatitis C progression is both more likely and more rapid in the presence of HIV infection and the hepatitis C viral load tends to be elevated. The

drug-related hepatotoxicity may be worse in those with HCV co-infection.

Assessment of co-infected patients requires full clinical and laboratory evaluation and staging of both infections. For HCV, both viral load and genotype will influence therapeutic decision-making.

Treatment options in HCV co-infection are similar for those infected with HCV alone, depending on stage of disease and HCV genotype. Pegylated interferon has greater efficacy than standard interferon and is combined with ribavirin. In HIV/HCV co-infected patients those with a CD4 count above 200 have a better chance of success. In general it is preferable to treat HCV first if HIV infection is stable, as this minimizes hepatotoxicity associated with HAART. However, if the CD4 count is low or the patient is at risk of HIV progression, HIV therapy should be instituted first. Protease inhibitors are being used in HIV/HCV co-infected patients. Patients should be vaccinated against both HBV and hepatitis A if not already immune.

Cytomegalovirus

CMV (see p. 99) has been the cause of considerable morbidity in HIV-infected individuals, especially in the later stages of disease when the CD4 count is consistently below 100. The availability of HAART has dramatically altered the epidemiology, as a majority of patients start antiretroviral drugs (ARVs) before they are at risk for CMV disease. The major problems encountered are retinitis, colitis, oesophageal ulceration, encephalitis and pneumonitis. CMV infection is associated with an arteritis, which may be the major pathogenic mechanism. CMV also causes polyradiculopathy and adrenalitis.

CMV retinitis

This occurs once the CD4 count is below 50. Although usually unilateral to begin with, the infection may progress to involve both eyes. Presenting features depend on the area of retina involved (loss of vision being most common with macular involvement) and include floaters, loss of visual acuity, field loss and scotomata, orbital pain and headache.

Examination of the fundus (Fig. 4.44) reveals haemorrhages and exudates, which follow the vasculature of the retina (so-called 'pizza pie' appearances). The features are highly characteristic and the diagnosis is made clinically. Retinal detachment and papillitis may occasionally occur. If untreated, retinitis spreads within the eye, destroying the retina within its path. Routine fundoscopy should be carried out on all HIV-infected patients to look for evidence of early

Figure 4.44 Untreated CMV retinitis.

infection. Any patient with symptoms of visual disturbance should have a thorough examination with pupils dilated and if no evident pathology is seen a specialist ophthalmologic opinion should be sought.

Treatment for CMV should be started as soon as possible, with either oral valganciclovir (900 mg twice daily), i.v. ganciclovir (5 mg/kg twice daily) or foscarnet (90 mg/kg twice daily) given intravenously for at least 3 weeks or until retinitis is quiescent. If immunosuppression is not reversed, reactivation is common, leading to blindness. The major side-effect of ganciclovir is myelosuppression and foscarnet is nephrotoxic. Maintenance therapy may be required until HAART is instituted and has improved immune competence. Valganciclovir, an oral prodrug of ganciclovir, is available which has some long-term benefit when used as maintenance therapy, but has a lower efficacy than intravenous ganciclovir. Ganciclovir can be given directly into the vitreous cavity but regular injections are required. A sustained-release implant of ganciclovir can be surgically inserted into the affected eye. Cidofovir is available for use when the above drugs are contraindicated. It has renal toxicity.

CMV gastrointestinal conditions

CMV colitis usually presents with abdominal pain, often generalized or in the left iliac fossa, diarrhoea which may be bloody, generalized abdominal tenderness and a low-grade fever. Dilated large bowel may be seen on abdominal X-ray. Sigmoidoscopy shows a friable or ulcerated mucosa; histology shows the characteristic 'owl's eye' cytoplasmic inclusion bodies (Fig. 4.16).

Treatment. Intravenous ganciclovir (5 mg/kg twice daily) for 14–28 days and when stable, optimization of HAART improves symptoms and the histological changes are reversed. Restoration of immune competence with HAART removes the need for maintenance therapy.

Other sites along the gastrointestinal tract are also prone to CMV infection, e.g. ulceration of the oesophagus, usually in the lower third, causes odynophagia. CMV can also cause hepatitis.

CMV neurological conditions

CMV encephalopathy has clinical similarities to that caused by HIV itself, although it tends to be more aggressive in its course. CMV polyradiculopathy can affect the lumbosacral roots, leading to muscle weakness and sphincter disturbance. The CSF has an increase in white cells, which surprisingly are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur. Diagnosis may be based on MRI imaging and CSF PCR. Therapy is with ganciclovir. HAART should be started after anti-CMV treatment.

Herpesviruses

Herpes simplex primary infection (see p. 97) occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in profoundly immunosuppressed individuals. Genital, oral and occasionally disseminated infection is seen. Viral shedding may be prolonged in comparison with immunocompetent patients.

Varicella zoster virus

Varicella zoster can occur at any stage of HIV but tends to be more aggressive and longer-lasting in the more immunosuppressed patient. Multidermatomal zoster may occur.

Therapy with aciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually due to thymidine kinase-deficient mutants) in

HIV-infected patients have become more common. Such strains may respond to foscarnet.

Herpesvirus 8 (HHV-8) is the causative agent of Kaposi's sarcoma (see p. 97).

Epstein-Barr virus

Patients with HIV have been shown to have high levels of EBV colonization (see p. 99). There are increased EBV titres in oropharyngeal secretions and high levels of EBV-infected B cells. The normal T-cell response to EBV is depressed in HIV. EBV is strongly associated with primary cerebral lymphoma and non-Hodgkin's lymphoma (see below). Oral hairy leucoplakia caused by EBV is a sign of immunosuppression first noted in HIV but now also recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale ridged lesion. Although usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified histologically and on electron microscopy. There is a variable response to aciclovir.

Human papillomavirus

HPV (see p. 100) produces genital, plantar and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is associated with the more rapid development of cervical and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinoma of the cervix or rectum in HIV-infected individuals. HPV vaccination is now available (see p. 169).

Polyomavirus

JC virus, a member of the papovavirus family, which infects oligodendrocytes, causes progressive multifocal leucoencephalopathy (PML) (see p. 101). This leads to demyelination particularly within the white matter of the brain. The features are of progressive neurological and/or intellectual impairment, often including hemiparesis or aphasia. The course is usually inexorably progressive but a stuttering course may be seen. Radiologically the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI (Fig. 4.45) is more sensitive than CT and reveals enhanced signal on T2-weighted images of the lesions. MRI appearances and JC virus detection by PCR in a CSF sample are usually sufficient for diagnosis and avoid the need for a tissue diagnosis requiring brain biopsy. There is no specific therapy. Effective HAART is the only intervention that has been shown to deliver both clinical and radiological remission.

Figure 4.45 MRI scans showing progressive multifocal leucoencephalopathy.

Bacterial infections

Bacterial infection in HIV is common. Cell-mediated immune responses normally control infection against intracellular bacteria, e.g. mycobacteria. The abnormalities of B-cell function associated with HIV lead to infections with encapsulated bacteria, as reduced production of IgG2 cannot protect against the polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers and so bacterial sepsis may be seen at early stages of HIV infection. *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis* infections are examples. Bacterial infection is often disseminated and, although usually amenable to standard antibiotic therapy, may reoccur. Long-term prophylaxis is required if recurrent infection is frequent.

Mycobacteria

Mycobacterium tuberculosis

Many parts of the world with a high prevalence of TB (see p. 859) also have high rates of HIV infection, e.g. Africa, both of which are increasing. The respiratory transmission of TB means both HIV-positive and HIV-negative people are being infected. TB can cause disease when there is only minimal immunosuppression and thus often appears early in the course of HIV infection. HIV-related TB frequently represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and hospital-acquired spread in HIV-infected populations.

The pattern of disease differs with immunosuppression:

- Patients with relatively well preserved CD4 counts have a clinical picture similar to that seen in HIV-negative patients with pulmonary infection.
- In more advanced HIV disease, atypical pulmonary presentations without cavitation and prominent hilar lymphadenopathy, or extrapulmonary TB affecting lymph nodes, bone marrow or liver occur. Bacteraemia may be present.

Diagnosis depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in HIV-positive individuals and is unreliable. Sputum microscopy may be negative even in pulmonary infection and culture techniques are the best diagnostic tool.

Treatment. *M. tuberculosis* infection usually responds well to standard treatment regimens, although the duration of therapy may be extended, especially in extrapulmonary infection. Multidrug resistance and extensive drug-resistant TB (see p. 845) is becoming a problem, particularly in the USA where it is becoming a health danger. Cases from HIV units in the UK have been reported. Compliance with antituberculous therapy needs to be emphasized. Treatment of TB (see below) is not curative and long-term isoniazid prophylaxis may be given. In patients from TB-endemic areas, primary prophylaxis may prevent emergence of infection.

Drug-drug interactions between antiretroviral and antituberculous medications are complex and are a consequence of enzyme induction or inhibition. Rifampicin is a potent inducer of cytochrome P450, which is also the route for metabolism of HIV protease inhibitors. Using both drugs together results in a reduction in circulating protease inhibitor with reduced efficacy and increased potential for drug resistance. Some protease inhibitors themselves block cytochrome P450, which leads to potentially toxic levels of rifampicin and problems such as uveitis and hepatotoxicity.

The non-nucleoside reverse transcriptase inhibitor class also interacts variably with rifamycins, requiring dose alterations. Additionally, there are overlapping toxicities between HAART regimens and antituberculous drugs, in particular hepatotoxicity, peripheral neuropathy and gastrointestinal side-effects. Rifabutin has a weaker effect on cytochrome P450 and may be substituted for rifampicin. Dose adjustments must be made for drugs used in this situation to take account of these interactions.

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) which can include exacerbation of symptoms, new or worsening clinical signs and deteriorating radiological appearances have been associated with the improvement of immune function seen in HIV-infected patients starting HAART in the face of *M. tuberculosis* infection. They are most commonly seen in the first few weeks after initiation of HAART in patients recovering from TB and can last several weeks or months. The syndrome does not reflect inadequate TB therapy and is not confined to any particular combination of antiretroviral agents. It is vital to exclude new pathology in this situation. However, delaying antiretroviral therapy increases the risks of further opportunistic events. Allowing at least 2 weeks of antituberculous therapy before commencing HAART allows some reduction in the burden of mycobacteria. If the CD4 count is <100 then antiretrovirals should be started at about 2 weeks of anti-TB medication. If the CD4 count is above 200 then initiation of HAART may wait for at least 6 weeks after the start of antituberculous therapy.

Mycobacterium avium-intracellulare

Atypical mycobacteria, particularly *M. avium-intracellulare* (MAI), generally appear only in the very late stages of HIV infection when patients are profoundly immunosuppressed. It is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the gastrointestinal tract or lungs with dissemination via infected macrophages.

The major clinical features are fevers, malaise, weight loss, anorexia and sweats. Dissemination to the bone marrow causes anaemia. Gastrointestinal symptoms may be prominent with diarrhoea and malabsorption. At this stage of disease patients frequently have other concurrent infections, so differentiating MAI is difficult on clinical grounds. Direct examination and culture of blood, lymph node, bone marrow or liver give the diagnosis most reliably.

Treatment. MAI is typically resistant to standard antituberculous therapies, although ethambutol may be useful. Drugs such as rifabutin in combination with clarithromycin or azithromycin reduce the burden of organisms and in some ameliorate symptoms. A common combination is ethambutol, rifabutin and clarithromycin. Addition of amikacin to a drug regimen may produce a good symptomatic response. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI, but no corresponding increase in survival has been shown.

Infections due to other organisms

Influenza virus A. Although no more frequent in HIV-infected peoples, influenza A (IVA) has been associated with an increased severity and complication rate in people with HIV, in particular those with low CD4 counts. Oseltamivir oral 75 mg twice daily for 5 days should be used as treatment. People with HIV should be vaccinated annually against IVA. Prophylaxis with oseltamivir is used in unvaccinated individuals with a CD4 count below 200 cells/ μ L.

Salmonellae (non-typhoidal) (see p. 120) are much less frequent pathogens in HIV infection if effective HAART is being used. Salmonellae are able to survive within macrophages, this being a major factor in their pathogenicity. Organisms are usually acquired orally and frequently result in disseminated infection. Gastrointestinal disturbance may be disproportionate to the degree of dissemination and once the pathogen is in the bloodstream any organ may be infected. *Salmonella* osteomyelitis and cystitis have been reported. Diagnosis is from blood and stool cultures. Despite increasing reports of resistance, a majority of isolates are sensitive to oral ciprofloxacin 500 mg twice daily for 5 days. Education on food hygiene should be provided.

Skin conditions such as folliculitis, abscesses and cellulitis are common and are usually caused by *Staph. aureus*. Periodontal disease, which may be necrotizing, causes pain and damage to the gums. It is more common in smokers, but no specific causative agent has been identified. Therapy is with local debridement and systemic antibiotics.

Strongyloides (see p. 156), a nematode found in tropical areas, may produce a hyperinfection syndrome in HIV-infected patients. Larvae are produced which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin may be used to control infection. Gram-negative septicaemia can develop (see Chapter 16).

Scabies (see Chapter 24) may be much more severe in HIV infection. It may be widely disseminated over the body and appear as atypical, crusted papular lesions known as 'Norwegian scabies', from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents such as lindane may fail and ivermectin has been used to good effect in some patients.

Neoplasms

HIV infection is associated with an increased risk of cancer, the most tightly linked being Kaposi's sarcoma, non-Hodgkin's lymphoma and cervical cancer, which are AIDS defining. Other cancers that have an association with infectious agents such as liver and anal cancer and Hodgkin's lymphoma, although not AIDS defining, are significantly more common in HIV-infected patients. Patterns are changing and there has been a marked reduction in AIDS-defining malignancy in association with effective antiretroviral therapy. The increased longevity for people with HIV increases the risks for development of cancers that are associated with older age. Some data suggests that HAART may provide some prevention benefits for non AIDS-defining malignancies.

Kaposi's sarcoma

Kaposi's sarcoma (KS) (see Chapter 24) in association with HIV (epidemic KS) behaves more aggressively than that associated with HIV-negative populations (endemic KS). The incidence has fallen significantly since the introduction of HAART. Human herpesvirus 8 (HHV-8) is involved in pathogenesis. KS skin lesions are characteristically pigmented, well circumscribed and occur in multiple sites. It is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects lymphatics and lymph nodes, the lung and gastrointestinal tract, giving rise to a wide range of symptoms and signs. Most patients with

Figure 4.46 Kaposi's sarcoma of the eyelid.

visceral involvement also have skin or mucous membrane lesions. Visceral KS carries a worse prognosis than that confined to the skin. Kaposi's sarcoma is seen around the eye (Fig. 4.46), particularly in the conjunctivae, which can lead to periorbital oedema.

HAART leads to regression of lesions. Local radiotherapy gives good results in skin lesions and is helpful in lymph node disease. In aggressive disease, systemic chemotherapy is indicated.

Lymphoma

A significant proportion of patients with HIV develop lymphoma, mostly of the non-Hodgkin's, large B-cell type. These are frequently extranodal, often affecting the brain, lung and gastrointestinal tract. Many of these tumours are strongly associated with Epstein-Barr virus (EBV), with evidence of expression of latent gene nuclear antigens such as EBNA 1–6, some of which are involved in the immortalization of B cells and drive a neoplastic pathway.

HIV-associated lymphomas are frequently very aggressive. Patients often present with systemic 'B' syndromes and progress rapidly despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis. Lymphomas occurring early in the course of HIV infection tend to respond better to therapy and carry a better prognosis, occasionally going into complete remission.

Cervical carcinoma

Women with HIV are at increased risk of cervical cancer caused by oncogenic subtypes of human papillomavirus (HPV). Annual cervical cytology is indicated to monitor for pre-malignant changes.

Prevention and control

High rates of new HIV infection continue and prevention interventions remain fundamental to the control of the epidemic. Combinations of behavioural, biomedical and structural approaches with interventions appropriate for the particular population at risk are required. Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host with disappointing results from trials of candidate agents.

Consistent condom use and education for behaviour change have been key strategies. Provision of clean injecting

equipment has been successful in those countries where it has been implemented.

Medically performed circumcision has been shown in African studies of HIV-negative heterosexual men to reduce the female-to-male transmission of HIV by at least 50%. A more modest reduction in HIV incidence in HIV-negative women following circumcision of HIV-positive male partners has been demonstrated but only at 2 years after the procedure.

Reduction of viral load in HIV-infected people by effective antiretroviral therapy has been shown to prevent onward transmission. Initiation of ART by HIV-infected individuals provided 96% reduction in risk of HIV transmission to HIV-uninfected heterosexual sexual partners. Vertical transmission can be reduced to negligible levels by the use of effective antiretroviral therapy in pregnant women.

Post-exposure prophylaxis (PEP) following sexual or occupational exposure can reduce the risk of infection if implemented promptly. Results from two trials of pre-exposure prophylaxis (PrEP) have demonstrated a modest reduction in risk in heterosexual women using intravaginal tenofovir gel and in MSM who take daily Truvada, although these drugs are not licensed for these indications.

Partner notification schemes are helpful but are sensitive and controversial. Availability and accessibility of confidential HIV testing provides an opportunity for individual health education and risk reduction to be discussed.

Understanding and changing behaviour is crucial but notoriously difficult, especially in areas that carry as many taboos as sex, HIV and AIDS. Poverty, social unrest and war all contribute to the spread of HIV. Political will, not always readily available, is required if progress in these areas is to occur.

INTRODUCTION

In developing countries, lack of food and poor usage of the available food can result in protein-energy malnutrition (PEM); 50 million pre-school African children have PEM. In developed countries, excess food is available and the most common nutritional problem is obesity.

Diet and disease are interrelated in many ways:

- **Excess energy intake contributes to a number of diseases**, including ischaemic heart disease and diabetes, particularly when high in animal (saturated) fat content.
- **There is a relationship between food intake and cancer**, as found in many epidemiological studies. An excess of energy-rich foods (i.e. fat and sugar containing), often with physical inactivity, plays a role in the development of certain cancers, while diets high in vegetables and fruits reduce the risk of most epithelial cancers. Numerous carcinogens, intentional additions (e.g. nitrates for preserving foods) or accidental contaminants (e.g. moulds producing aflatoxin and fungi) may also be involved in the development of cancer.
- **The proportion of processed foods eaten may affect the development of disease**. Some processed convenience foods have a high sugar and fat content and therefore predispose to dental caries and obesity, respectively. They also have a low fibre content, and dietary fibre can help in the prevention of a number of diseases (see p. 199).
- **Long-term undernutrition is implicated in disease** by some epidemiological studies, for example low growth rates in utero are associated with high death rates from cardiovascular disease in adult life.

In the UK, dietary reference values for food and energy and nutrients are stated as *reference nutrient intakes* (RNIs), on the basis of data from the Food and Agriculture Organization (FAO-WHO), United Nations University (UNU) expert

committee, and elsewhere. The RNI is sufficient or more than sufficient to meet the nutritional needs of 97.5% of healthy people in a population. Most people's daily requirements are less than this, and so an *estimated average requirement* (EAR) is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI) which fails to meet the requirements of 97.5% of the population is also given. The RNI figures quoted in this chapter are for the age group 19–50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

WATER AND ELECTROLYTE BALANCE

Water and electrolyte balance is dealt with fully in Chapter 13. About 1 L of water is required in the daily diet to balance insensible losses, but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90–440 mmol (2–10 g). These are needlessly high intakes of sodium which are thought by some to play a role in causing hypertension (see p. 778).

DIETARY REQUIREMENTS

Energy

Food is necessary to provide the body with energy (Fig. 5.1). The SI unit of energy is the joule (J), and 1 kJ = 0.239 kcal. The conversion factor of 4.2 kJ, equivalent to 1.00 kcal, is used in clinical nutrition.

Energy balance

Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple, but accurate, way of indicating differences in energy balance.

FURTHER READING

Panel on Dietary Reference Values of the Committee on Medical Aspects of Food Policy. *Dietary Reference for Food Energy and Nutrients for the United Kingdom (Report 41DOH)*. London: HMSO; 1991.

Figure 5.1 The production of energy from the main constituents of food. Alcohol produces up to 5% of total calories, but the variation between individuals is wide. 1 mol of glucose produces 36 mol of ATP. NEFA, non-esterified fatty acids; ATP, adenosine triphosphate; TCA, tricarboxylic acid.

Energy requirements

There are two approaches to assessing energy requirements for subjects who are weight stable and close to energy balance:

- Assessment of energy intake
- Assessment of total energy expenditure.

Energy intake

This can be estimated from dietary surveys and in the past this has been used to decide daily energy requirements. However, measurement of energy expenditure gives a more accurate assessment of requirements.

Energy expenditure

Daily energy expenditure (Fig. 5.2) is the sum of:

- The basal metabolic rate (BMR)
- The thermic effect of food eaten
- Occupational activities
- Non-occupational activities.

Total energy expenditure can be measured using a double-labelled water technique. Water containing the stable isotopes ^2H and ^{18}O is given orally. As energy is expended carbon dioxide and water are produced. The difference

Figure 5.2 Daily energy expenditure in an active and a sedentary 70 kg adult. BMR, basal metabolic rate; DIT, dietary induced thermogenesis; PAR, physical activity ratio.

Table 5.1 Equations for the prediction of basal metabolic rate (in MJ/day)

Age range (years)	Equation for predicting BMR ^a	95% confidence limits
Men		
10–17	$0.0740 \times (\text{wt}) + 2.754$	± 0.88
18–29	$0.0630 \times (\text{wt}) + 2.896$	± 1.28
30–59	$0.0480 \times (\text{wt}) + 3.653$	± 1.40
60–74	$0.0499 \times (\text{wt}) + 2.930$	N/A
75+	$0.0350 \times (\text{wt}) + 3.434$	N/A
Women		
10–17	$0.0560 \times (\text{wt}) + 2.898$	± 0.94
18–29	$0.0620 \times (\text{wt}) + 2.036$	± 1.00
30–59	$0.0340 \times (\text{wt}) + 3.538$	± 0.94
60–74	$0.0386 \times (\text{wt}) + 2.875$	N/A
75+	$0.0410 \times (\text{wt}) + 2.610$	N/A

Data from Department of Health, 1991. BMR, basal metabolic rate.

^aBodyweight (wt) in kg.

between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2–3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to estimate CO_2 production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by a minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO_2 . Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

Basal metabolic rate. The BMR can be calculated by measuring oxygen consumption and CO_2 production, but it is more usually taken from standardized tables (Table 5.1) that only require knowledge of the subject's age, weight and sex.

Physical activity. The physical activity ratio (PAR) is expressed as multiples of the BMR for both occupational and non-occupational activities of varying intensities (Table 5.2).

Total daily energy expenditure = $\text{BMR} \times [\text{Time in bed} + (\text{Time at work} \times \text{PAR}) + (\text{Non-occupational time} \times \text{PAR})]$.

Thus, for example, to determine the daily energy expenditure of a 69-year-old, 50 kg female doctor, with a BMR of 4805 kJ/day spending one-third of a day sleeping, working

Table 5.2 Physical activity ratio (PAR) for various activities (expressed as multiples of BMR)

	PAR
Occupational activity	
Professional/housewife	1.7
Domestic helper/sales person	2.7
Labourer	3.0
Non-occupational activity	
Reading/eating	1.2
Household/cooking	2.1
Gardening/golf	3.7
Jogging/swimming/football	6.9

and engaged in non-occupational activities, the latter at a PAR of 2.1, the following calculation ensues:

$$= (4805 \text{ kJ/day}) \times [0.3 + (0.3 \times 1.7) + (0.3 \times 2.10)]$$

$$= 6919 \text{ kJ (1655 kcal/day)}.$$

In the UK, the estimated 'average' daily energy requirement is:

- for a 55-year-old female – 8100 kJ (1940 kcal)
- for a 55-year-old male – 10600 kJ (2550 kcal).

This is at present made up of about 50% carbohydrate, 35% fat, 15% protein \pm 5% alcohol. In developing countries, however, carbohydrate may be >75% of the total energy input, and fat <15% of the total energy input.

Energy requirements increase during the growing period, with pregnancy and lactation, and sometimes following infection or trauma. In general, the increased BMR associated with inflammatory or traumatic conditions is counteracted or more than counteracted by a decrease in physical activity, so that total energy requirements are not increased.

In the basal state, energy demands for resting muscle are 20% of the total energy required, abdominal viscera 35–40%, brain 20% and heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.

Energy stores

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Figure 5.3 shows that fat accounts for the largest reserves of energy in both lean and obese subjects. The size of the stores determines survival during starvation.

Bodyweight

Bodyweight depends on energy balance. Intake depends not only on food availability but also on a number of complex interrelationships that include the stimulus of good food, the role of hunger, metabolic changes (e.g. hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their bodyweight constant within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure. A gain or loss of energy of 25–29 MJ (6000–7000 kcal) would respectively increase or decrease bodyweight by approximately 1 kg.

Protein

In the UK, the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80–100 g of protein per day.

The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis.

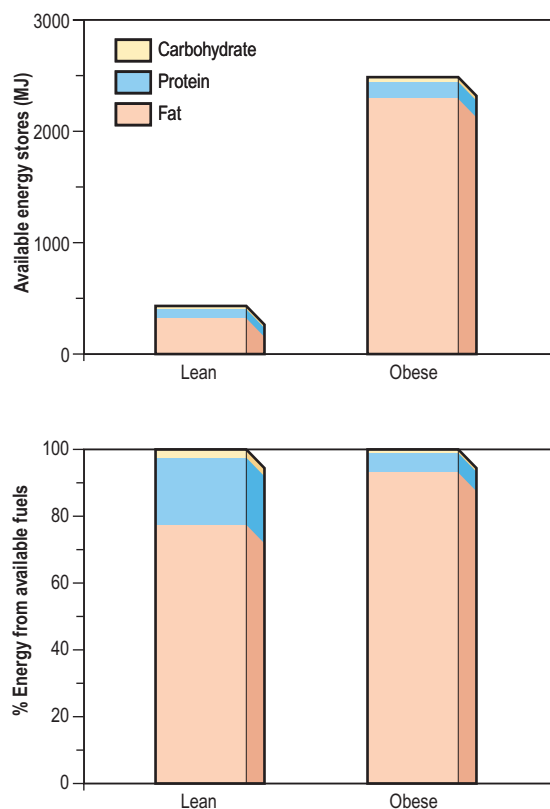

Figure 5.3 Available energy reserves from different fuels expressed in MJ (upper) and as a percentage of total (lower) in a lean hypothetical 70 kg adult and an obese 140 kg adult.

In order to maintain nitrogen balance, at least 40–50 g of protein are needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 h using the following equation:

Grams of protein required = Urinary nitrogen \times 6.25 (most proteins contain about 16% of nitrogen).

In practice, urinary urea is more easily measured and forms 80–90% of the total urinary nitrogen (N). In healthy individuals urinary nitrogen excretion reflects protein intake. However, excretion does not match intake in catabolic conditions (negative N balance) or during growth or repletion following an illness (positive N balance).

Protein contains many **amino acids**:

- **Indispensable (essential)**: there are nine amino acids that cannot be synthesized and must be provided in the diet: tryptophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine, leucine.
- **Dispensable (non-essential)**: amino acids that can be synthesized in the body (some may still be needed in the diet unless adequate amounts of their precursors are available).

Animal proteins (e.g. in milk, meat, eggs) contain a good balance of all indispensable amino acids, but many proteins from vegetables are deficient in at least one indispensable amino acid. In developing countries, protein intake derives mainly from vegetable proteins. By combining foodstuffs with different low concentrations of indispensable amino acids (e.g. maize with legumes), protein intake can be adequate provided enough vegetables are available.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake, but also because of inadequate energy intake. When there is loss of

Introduction

Water and electrolyte balance

Dietary requirements

energy from the body, more protein is directed towards oxidative pathways and eventually gluconeogenesis for energy.

Role of amino acids

- Glutamine is quantitatively the most significant in the circulation and in inter-organ exchange.
- Alanine is released from muscle; it is deaminated and converted into pyruvic acid before entering the citric acid cycle.
- Homocysteine is a sulphur-containing amino acid which is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease (see p. 728).
- Amino acids are utilized to synthesize products other than protein or urea. For example:
 - Glycine is required for haem production
 - Tyrosine is required for melanin and thyroid hormones
 - Glutamine, aspartate and glycine are required for nucleic acid bases
 - Glutamate, cysteine and glycine are required for glutathione, which is part of the defence system against free radicals.

Fat

Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation (Table 5.3). The hydrogen molecules related to the double bonds can be in the *cis* or the *trans* position; most natural fatty acids in food are in the *cis* position (Box 5.1).

Table 5.3 The main fatty acids in foods

Fatty acid	No. of carbon atoms:No. of double bonds	Position of double bonds ^a
Saturated		
Lauric	C12:0	
Myristic	C14:0	
Palmitic	C16:0	
Stearic	C18:0	
Monounsaturated		
Oleic	C18:1	(<i>n</i> -9)
Elaidic	C18:1	(<i>n</i> -9 <i>trans</i>)
Polyunsaturated		
Linoleic	C18:2	(<i>n</i> -6)
α -Linolenic	C18:3	(<i>n</i> -3)
Arachidonic	C20:4	(<i>n</i> -6)
Eicosapentaenoic	C20:5	(<i>n</i> -3)
Docosahexaenoic	C22:6	(<i>n</i> -3)

^aPositions of the double bonds (designated either *n* as here or ω) are shown counted from the methyl end of the molecule. All double bonds are in the *cis* position except that marked *trans*.

Box 5.1 Dietary sources of fatty acids

Type of acid	Sources
Saturated fatty acids	Mainly animal fat
<i>n</i> -6 fatty acids	Vegetable oils and other plant foods
<i>n</i> -3 fatty acids	Vegetable foods, rapeseed oil, fish oils
<i>trans</i> fatty acids	Hydrogenated fat or oils, e.g. in margarine, cakes, biscuits

The *essential fatty acids* (EFAs) are linoleic and α -linolenic acid, both of which are precursors of prostaglandins. Eicosapentaenoic and docosahexaenoic acid are also necessary, but can be made to a limited extent in the tissues from linoleic and linolenic acid, and thus a dietary supply is not essential.

Synthesis of triglycerides, sterols and phospholipids is very efficient. Even with low-fat diets subcutaneous fat stores can be normal.

Dietary fat provides 37 kJ (9 kcal) of energy per gram. A high-fat intake has been implicated in the causation of:

- cardiovascular disease
- cancer (e.g. breast, colon and prostate)
- obesity
- type 2 diabetes.

The data on causation are largely epidemiological and disputed by many. Nevertheless, it is often suggested that the consumption of saturated fatty acids should be reduced, accompanied by an increase in monounsaturated fatty acids (the 'Mediterranean diet') or polyunsaturated fatty acids. Any increase in polyunsaturated fats should not, however, exceed 10% of the total food energy, particularly as this requires a big dietary change.

Trans fats (partly hydrogenated fatty acids)

Increased consumption of hydrogenated vegetable and fish oils in margarines has led to increased *trans* fatty acid consumption. *Trans fatty acids* (also called *trans* fats) behave as if they were saturated fatty acids, increasing circulating LDL and decreasing HDL cholesterol concentrations, which in turn increase the risk of cardiovascular disease. In most countries, nutrition labels for all conventional foods and supplements must indicate the *trans* fatty acid content. The usage of *trans* fatty acids from partially hydrogenated oils has now been banned in many countries.

Polyunsaturated fatty acids

The *n*-6 polyunsaturated fatty acids (PUFA) are components of membrane phospholipids, influencing membrane fluidity and ion transport. They also have antiarrhythmic, anti-thrombotic and anti-inflammatory properties, all of which are potentially helpful in preventing cardiovascular disease.

The *n*-3 PUFA increase circulating high-density lipoprotein (HDL) cholesterol and lower triglycerides, both of which might reduce cardiovascular risk. Some of the actions of *n*-3 PUFA are mediated by a range of leukotrienes and eicosanoids, which differ in pattern and functions from those produced from *n*-6 PUFA.

Epidemiological studies and clinical intervention studies suggest that *n*-3 PUFA may have effects in the secondary prevention of cardiovascular disease and 'all-cause mortality' (e.g. 20–30% reduction in mortality from cardiovascular disease according to some studies). The benefits, which have been noted as early as 4 months after intervention, have been largely attributed to the antiarrhythmic effects of *n*-3 PUFA, but some work suggests that *n*-3 PUFA, administered as capsules, can be rapidly incorporated into atherosclerotic plaques, stabilizing them and preventing rupture. Whether these effects are due directly to *n*-3 PUFA or other changes in the diet is still debated.

The *GISSI Prevention Trial*, which followed over 11 000 patients for 3.5 years after a myocardial infarction, administered fish oils (eicosapentaenoic acid, EPA and docosahexaenoic acid, DHA) in the form of capsules and demonstrated a striking benefit in reducing mortality. The effects of vitamin E (300 mg α -tocopherol/day) were also studied, but no benefit was found.

Box 5.2 Recommended healthy dietary intake

Dietary component	Approximate amounts given as % of total energy unless otherwise stated	General hints
Total carbohydrate	55 (55–75)	Increase fruit, vegetables, beans, pasta, bread
Free sugar	10 (<10)	Decrease sugary drinks
Protein	15 (10–15)	Decrease red meat (see fat below)
Total fat	30 (15–30)	Increase vegetable (including olive oil) and fish oil and decrease animal fat
Saturated fatty acids	10 (<10)	Mainly oleic acid (<i>n</i> -6)
Cis-mono unsaturated fatty acids	20	Both <i>n</i> -6 and <i>n</i> -3 PUFA
Cis-polyunsaturated fatty acids	6	
Approximate amounts		
Cholesterol	<300 (<300) mg/day	Decrease meat and eggs
Salt	<6 (<5) g/day	Decrease prepared meats and do not add extra salt to food
Total dietary fibre	30 (>25) g/day	Increase fruit and vegetables and wholegrain foods

Values in parentheses are goals for the intake of populations, as given by the WHO (including populations who are already on low-fat diets). Some of the extreme ranges are not realistic short-term goals for developed countries, e.g. 75% of total energy from carbohydrate and 15% fat. When total energy intake is 2500 kcal (10500 kJ) per day, 55% of intake comes from carbohydrate (344 g, i.e. 1376 kcal (5579 kJ)) and 30% from fat (83 g, i.e. 747 kcal (3137 kJ)).

Recommendations for fat intake

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total *n*-3 PUFA (several fold increase in the intake of fish oils, and a 50% increase in the intake of α -linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of eating certain types of fish, which increase the risk of mercury poisoning and possibly other toxicities.

The current recommendations for fat intake for the UK are shown in Box 5.2.

Cholesterol

Cholesterol is found in all animal products. Eggs are particularly rich in cholesterol, which is virtually absent from plants. The average daily intake in the UK is 300–500 mg. Cholesterol is also synthesized (see p. 306) and only very high or low dietary intakes will significantly affect blood levels.

Essential fatty acid deficiency

Essential fatty acid deficiency may accompany protein-energy malnutrition (PEM), but it has been clearly defined as a clinical entity only in patients on long-term parenteral nutrition given glucose, protein and no fat. Alopecia, thrombocytopenia, anaemia and dermatitis occur within weeks with an increased ratio of triene (*n*-9) to tetraene (*n*-6) in plasma fatty acids.

Carbohydrate

Carbohydrates are readily available in the diet, providing 17 kJ (4 kcal) per gram of energy (15.7 kJ (3.75 kcal) per gram monosaccharide equivalent). Carbohydrate intake comprises:

- polysaccharide starch
- disaccharides (mainly sucrose)
- monosaccharides (glucose and fructose).

Carbohydrate is cheap compared with other foodstuffs; a great deal is therefore eaten, usually more than required.

Dietary fibre

Dietary fibre, which is largely *non-starch polysaccharide* (NSP) (entirely NSP according to some authorities), is often removed in the processing of food. This leaves highly refined carbohydrates such as sucrose which contribute to the development of dental caries and obesity. Lignin is included in dietary fibre in some classification systems, but it is not a polysaccharide. It is only a minor component of the human diet.

The principal classes of NSP are:

- Cellulose
- Hemicelluloses
- Pectins
- Gums.

None of these are digested by gut enzymes. However, NSP is partly broken down in the gastrointestinal tract, mainly by colonic bacteria, producing gas and volatile fatty acids, e.g. butyrate.

All plant food, when unprocessed, contains NSP, so that all unprocessed food eaten will increase the NSP content of the diet. Bran, the fibre from wheat, provides an easy way of adding additional fibre to the diet: it increases faecal bulk and is helpful in the treatment of constipation.

The average daily intake of NSP in the diet is approximately 16 g. NSP deficiency is accepted as an entity by many authorities and it is suggested that the total NSP be increased to up to 30 g daily. This could be achieved by increased consumption of bread, potatoes, fruit and vegetables, with a reduction in sugar intake in order not to increase total calories. Each extra gram of fibre daily adds approximately 3–5 g to the daily stool weight. Pectins and gums have also been added to food to slow down monosaccharide absorption, particularly useful in type 2 diabetes.

Eating a diet rich in plant foods (fruits, vegetables, cereals and whole grain – the main sources of dietary fibre) is generally recommended for general health promotion, including protection against ischaemic heart disease, stroke and certain types of cancers. This has been attributed to a lipid lowering effect, the presence of protective substances, such as vitamin and non-vitamin antioxidants and other vitamins such as folic acid, which is linked to homocysteine metabolism, a risk factor for cardiovascular disease. Fermentation

of fibre in the colon may protect against development of colonic cancer. However, associated lifestyle factors such as low physical activity may also help explain some of those associations.

Health promotion

Many chronic diseases – particularly obesity, diabetes mellitus and cardiovascular disease – cause premature mortality and morbidity and are potentially preventable by dietary change. This is a global problem, e.g. obesity affects one in nine adults in the world with the BMI being now similar in high- and middle-income groups. Reduction in salt and fat intake, combined with exercise and stopping smoking, would have a major effect on the health of the population.

Box 5.2 suggests the composition of the 'ideal healthy diet'. The values given are based on the principle of:

- reducing total fat in the diet, particularly saturated fat
- increasing consumption of fish which contain *n*-3 (or ω -3) polyunsaturated fatty acids
- increasing intake of whole-grain cereals, green and orange vegetables and fruits, leading to an increase in fibre and antioxidants.

Reductions in dietary sodium and cholesterol have also been suggested. There would be no disadvantage in this, and most studies have suggested some benefit.

Fortification of foods

Fortification of foods with specific nutrients is common. In the UK, *margarine and milk* are fortified with vitamins A and D, *flour* with calcium, iron, thiamin and niacin and *breakfast cereals* with several vitamins and iron. Not all substances used in fortification have nutritive value. For example, *Olestra* is a polymer of sucrose and six or more triglycerides which has been introduced to combat obesity. It is not absorbed and is therefore used particularly in savoury snack foods (where it has FDA approval) as a 'fake fat'. Therefore, it results in a reduction in total calories. It has side-effects, e.g. loose stools, abdominal cramps, and its use is being carefully monitored.

Nutrient goals and dietary guidelines

The interests of the individual are often different from those associated with government policy. A distinction needs to be made between nutrient goals and dietary guidelines:

- *Nutrient goals* refer to the national intakes of nutrients that are considered appropriate for optimal health in the population.
- *Dietary guidelines* refer to the dietary methods used to achieve these goals.

Since dietary habits in different countries vary, dietary guidelines may also differ, even when the nutrient goals are the same. Nutrient goals are based on scientific information that links nutrient intake to disease. Although the information is incomplete, it includes evidence from a wide range of sources, including experimental animal studies, clinical studies and both short-term and long-term epidemiological studies.

PROTEIN-ENERGY MALNUTRITION (PEM)

Developed countries

Starvation uncomplicated by disease is relatively uncommon in developed countries, although some degree of

Table 5.4 Common conditions associated with protein-energy malnutrition

Sepsis	Dementia
Trauma	Malignancy
Surgery, particularly of GI tract with complications	Any very ill patient
GI disease, particularly involving the small bowel	Severe chronic inflammatory diseases
	Psychosocial: poverty, social isolation, anorexia nervosa, depression

undernourishment is seen in very poor areas. Most nutritional problems occurring in the population at large are due to eating wrong combinations of foodstuffs, such as an excess of refined carbohydrate or a diet low in fresh vegetables. Undernourishment associated with disease is common in hospitals and nursing homes, and **Table 5.4** gives a list of conditions in which malnutrition is often seen. Surgical complications, with sepsis, are a common cause. Many patients are admitted to hospital undernourished, and a variety of chronic conditions predispose to this state (**Table 5.5**).

The majority of the weight loss, leading to malnutrition, is due to poor intake secondary to the anorexia associated with the underlying condition. Disease may also contribute by causing malabsorption and increased catabolism, which is mediated by complex changes in cytokines, hormones, side-effects of drugs, and immobility. The elderly are particularly at risk of malnutrition because they often suffer from diseases and psychosocial problems such as social isolation or bereavement (**Table 5.5**).

Pathophysiology of starvation (**Fig. 5.4**)

In the first 24 h following low dietary intake, the body relies for energy on the breakdown of hepatic glycogen to glucose. Hepatic glycogen stores are small and therefore gluconeogenesis is soon necessary to maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glycerol and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.

Lipolysis, the breakdown of the body's fat stores, also occurs. It is inhibited by insulin, but the level of this hormone falls off as starvation continues. The stored triglyceride is hydrolysed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids that can be used directly as a fuel or oxidized in the liver to ketone bodies.

Adaptive processes take place as starvation continues, to prevent the body's available protein being completely utilized. There is a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies. Gluconeogenesis in the liver decreases as does protein breakdown in muscle, both of these processes being inhibited directly by ketone bodies. Most of the energy at this stage comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver, and glutamine in the kidney.

The metabolic response to prolonged starvation differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than lean subjects. It can be regarded as an adaptation which depends on the

Table 5.5 Nutritional consequences of disease and the underlying risk factors (physical/psychosocial problems)

Risk factors	Consequence
Underlying disease Almost any moderate/severe chronic disease Recovery from severe acute/subacute disease	Anorexia, increased requirements for some nutrients, and other effects indicated below (depending on condition)
Physical problems Muscle weakness (respiratory and peripheral muscles) and/or incoordination Severe arthritis in hands and arms Swallowing problem (neurological causes), painful or obstructive conditions of mouth and gastrointestinal tract (GIT) GIT symptoms (e.g. nausea, vomiting, diarrhoea, jaundice) Sensory deficit (e.g. impaired sight, hearing and other deficits)	Problems with shopping, cooking and eating Inadequate food intake, and/or risk of aspiration pneumonia Food aversion, malabsorption (small bowel disease), anorexia Difficulties in shopping, cooking and/or decreased intake of food
Psychosocial problems Loneliness, depression, bereavement, confusion, living alone, poverty, alcoholism, drug addiction	Self-neglect, inadequate intake of food or quality of food
Multiple drug use (polypharmacy)	Indicates severe disease or multiple physical and psychosocial problems; drugs may lead to confusion, sedation, depression and GIT side-effects (including malabsorption of nutrients)

**Figure 5.4** Metabolism in (a) the fed and (b) the fasted state. NEFA, non-esterified fatty acids.

composition of the initial reserves (Fig. 5.3). This means that deterioration in body function is more rapid in lean subjects. Furthermore, survival time is much less in lean subjects (~2 months), compared to the obese (can be at least several months).

Following trauma or shock, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) stimulate the ubiquitin-proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation, there is a decrease in BMR, while in inflammatory and traumatic disease the BMR is often increased. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

Regulation of metabolism

Tissue metabolism is regulated by multiple coordinated processes. Some are rapid involving nerves, whilst others are slower involving circulating substrates and hormones. Factors include:

- **Circulating substrate concentrations.** The uptake and metabolism of ketone bodies, which serve as the major fuel for the brain during prolonged starvation, is primarily determined by the circulatory concentration which can increase up to 5 mmol/L or more. The liver is

responsible for producing ketone bodies, the production of which is in turn controlled by the availability of fatty acids derived from adipose tissue. Substrates may also compete with each other for metabolism, for example glucose competes with non-esterified fatty acids for uptake and metabolism in muscle and heart (the glucose-fatty acid cycle) and this is independent of hormones.

- **Blood flow.** The delivery of substrates (and other signals) to tissues depends not only on their circulating concentration but also on the blood flow to tissues. In many tissues there is coupling between metabolic activity and blood flow, with arterioles regulating blood flow to the tissue according to demand, e.g. blood flow to muscle increases during exercise.
- **Signals.** Hormones and other signals, such as cytokines (see below), regulate intracellular metabolism.

Insulin/glucagon ratios in the fed and fasted state

In the fed state, insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein and fat, and inhibits lipolysis and gluconeogenesis.

In the fasted state, insulin/glucagon ratios are low. Glucagon acts mainly on the liver and has no action on

muscle. It increases glycogenolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids that can then act as a major source of energy.

Proportion of lean to fat tissue

During weight loss uncomplicated by disease, the proportion of lean to fat tissue loss (or proportion of energy derived from protein metabolism) is greater in lean than overweight/obese individuals.

During acute disease, loss of lean tissue, which is associated with protein oxidation, can be particularly rapid. Hormones such as corticosteroids, proinflammatory cytokines and insulin resistance are all involved.

Role of cytokines

The metabolic response to trauma, injury and inflammation depends on the balance between proinflammatory (e.g. tumour necrosis factor, TNF; interleukin-2, IL-2) and anti-inflammatory cytokines (e.g. IL-10), and the production of many of these cytokines is influenced by genetic polymorphisms. Since many chronic diseases, including atherosclerosis, have an inflammatory component, these changes have wide-reaching metabolic implications.

Cytokines such as IL-1, IL-6 and TNF play a significant role in regulating metabolism. In acute diseases they contribute to the catabolic process, glycogenolysis, and acute-phase protein synthesis. TNF, which inhibits lipoprotein lipase, is one of a number of 'cachexia factors' in patients with cancer.

It is unclear how these cytokines interact with central feeding pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, so there is a reduced drive to feeding.

Clinical features

Patients are sometimes seen with loss of weight or malnutrition as the primary symptom (failure to thrive in children). Mostly, however, malnourishment is only seen as an accompaniment of some other disease process, such as malignancy. Severe malnutrition is seen mainly with advanced organic disease or after surgical procedures followed by complications. Three key features which help in the detection of chronic protein-energy malnutrition (PEM) in adults are listed in Box 5.3.

Other factors that may suggest PEM include:

- History of decreased food intake/loss of appetite
- Clothes becoming loosely fitting (weight loss) and a general appearance indicating obvious wasting
- Physical and psychosocial disturbances likely to have contributed to the weight loss.

The factors listed in Box 5.3 act as a link between detection and management (Fig. 5.5, the 'Malnutrition Universal Screening Tool'). If the underlying physical or psychosocial problems are not adequately addressed, treatment may not be successful.

PEM leads to a depression of the immunological defence mechanism, resulting in a decreased resistance to infection. It also detrimentally affects muscle strength and fatigue, reproductive function (e.g. in anorexia nervosa, which is

Box 5.3 Key features in detection of chronic protein-energy malnutrition (PEM) in developed countries

- The body mass index (BMI):**
 - Probable chronic PEM: $<18.5 \text{ kg/m}^2$
 - Possible chronic PEM: $18.5\text{--}20 \text{ kg/m}^2$
 - Little or no risk of chronic PEM: $>20 \text{ kg/m}^2$.

In patients with oedema or dehydration the BMI may be somewhat misleading.
- Weight loss in previous 3–6 months:** $>10\%$, high risk; $5\text{--}10\%$, possible risk; $<5\%$ low/no risk of developing PEM.
- Acute disease effect:** diseases that have resulted or are likely to result in no dietary intake for >5 days are associated with a high risk of malnutrition (e.g. prolonged unconsciousness, persistent swallowing problems after a stroke, or prolonged ileus after abdominal surgery).

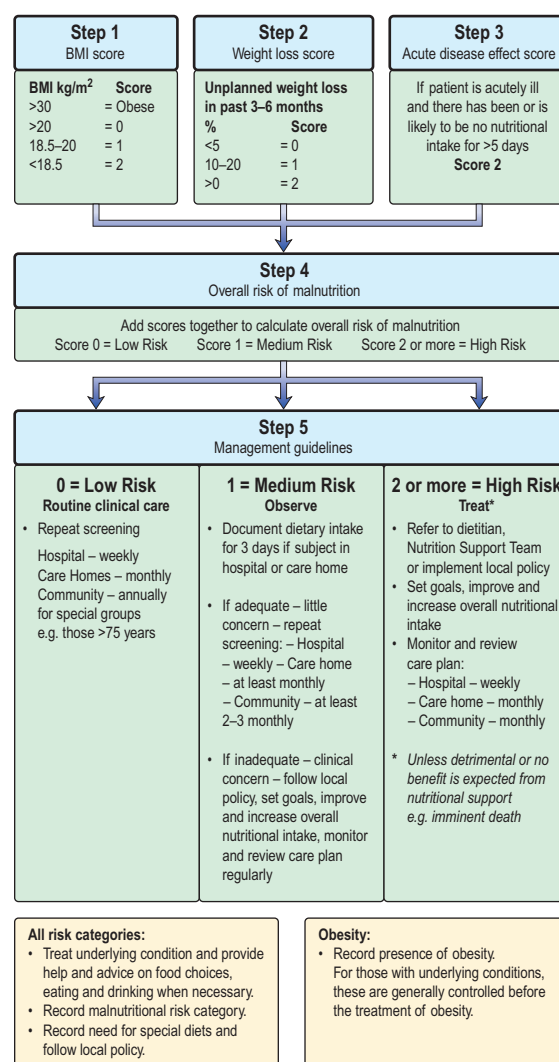

Figure 5.5 'Malnutrition Universal Screening Tool' ('MUST') (with permission from the British Association for Parenteral and Enteral Nutrition (BAPEN), at: <http://www.bapen.org.uk>).

common in adolescent girls; p. 1188), wound healing, and psychological function (depression, anxiety, hypochondriasis, loss of libido).

In children, growth failure is a key element in the diagnosis of PEM. New WHO standards for optimal growth in children

0–4 years have been adopted by developing and developed countries. They aim to reflect optimal rather than prevailing growth in both developed and developing countries, since they involved a healthy pregnancy and children born to non-smoking, relatively affluent mothers who breast-fed their children exclusively or predominantly for the first 6 months of life. The general principles of management of severe PEM in children are similar in developed and developing countries but resources are required to manage the problems once identified (see p. 205).

Treatment

When malnutrition is obvious and the underlying disease cannot be corrected at once, some form of nutritional support is necessary (see also pp. 221, 223). Nutrition should be given enterally if the gastrointestinal tract is functioning adequately. This can most easily be done by encouraging the patient to eat more often and by giving a high-calorie supplement. If this is not possible, a liquefied diet may be given intragastrically via a fine-bore tube or by a percutaneous endoscopic gastrostomy (PEG). If both of these measures fail, parenteral nutrition is given.

Developing countries

The International Union of Nutritional Sciences, with support from the International Pediatric Association, launched a global Malnutrition Task Force in 2005 to ensure that an integrated system of prevention and treatment of malnutrition is actively supported.

In many areas of the world, people are on the verge of malnutrition due to extreme poverty. In addition, if events such as drought, war or changes in political climate occur, millions suffer from starvation. Although the basic condition of PEM is the same in all parts of the world from whatever cause, malnutrition resulting from long periods of near-total starvation produces unique clinical appearances in children virtually never seen in high-income countries. The term 'protein-energy malnutrition' covers the spectrum of clinical conditions seen in adults and children. Children under 5 years may present with the following:

- **Kwashiorkor** occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalized oedema with skin pigmentation and thickening (Fig. 5.6b). The hair is dry, sparse and may become reddish or yellow in colour. The abdomen is distended owing to hepatomegaly and/or ascites. The serum albumin is always low. The exact cause is unknown, but theories related to diet (low in protein, and high in carbohydrate) and free radical damage in the presence of inadequate antioxidant defences have been proposed.
- **Marasmus** is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (Fig. 5.6a). The child is not so apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.

A classification of severe malnutrition by the *World Health Organization (WHO)* (Table 5.6) makes no distinction between kwashiorkor and marasmus, because their approach to treatment is similar. The WHO classification of chronic

b

Figure 5.6 Malnourished children: (a) marasmus and (b) kwashiorkor. (Courtesy of Dr Paul Kelly.)

Table 5.6 Classification of childhood malnutrition

	Moderate malnutrition	Severe malnutrition ^a
Symmetrical oedema	No	Yes: oedematous malnutrition ^b
Weight-for-height SD score	−3 to −2 (70–79%) ^c	<−3 (<70%) ^c (severe wasting) ^d
Height-for-age SD score	−3 to −2 (85–89%) ^c	<−3 (<85%) ^c (severe stunting)

^aThe diagnoses are not mutually exclusive.

^bOlder classifications use the terms kwashiorkor and marasmic-kwashiorkor instead.

^cPercentage of the median National Centre for Health Statistics/WHO reference.

^dCalled marasmus (without oedema) in the Wellcome classification and grade II in the Gomez classification.

undernutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between -2 and -3 (between 3 and 2 standard deviation scores below the median – corresponding to a value between 0.13 and 2.3 centile) can be regarded as being at moderate risk of undernutrition, and below an SD score of -3 , of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological) and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

Starvation in adults may lead to extreme loss of weight depending upon the severity and duration. They may crave for food, are apathetic and complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. The WHO classification is based on body mass index (BMI), with a value $<18.5 \text{ kg/m}^2$ indicating malnutrition (severe malnutrition if $<16.0 \text{ kg/m}^2$).

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

Investigations

These are not always practicable in certain settings in the developing world.

- **Blood tests:**
 - Anaemia due to folate, iron and copper deficiency is often present, but the haematocrit may be high owing to dehydration
 - Eosinophilia suggests parasitic infestation
 - Electrolyte disturbances are common
 - Malarial parasites should be sought
 - HIV tests.
- **Stools** should be examined for parasitic infestations.
- **Chest X-ray** – tuberculosis is common and is easily missed if a chest X-ray is not performed.

Treatment

Treatment must involve the provision of protein and energy supplements and the control of infection. The approach to treatment of children is described below. Adults do not usually suffer such severe malnutrition, but the same general principles of treatment should be followed.

Resuscitation and stabilization

The severely ill child will require:

- Correction of fluid and electrolyte abnormalities, but intravenous therapy should be avoided if possible because of the danger of fluid overload
- Treatment of shock with oxygen
- Treatment of hypoglycaemia (blood glucose $<3 \text{ mmol/L}$), hypothermia (reduce heat loss, and provide additional heat if necessary) and infection (antibiotics) – these often co-exist.

The standard WHO **oral hydration solution** has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can also be produced by modification of the standard WHO oral hydration solution.

Infection is common (Box 5.4). Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimalarial therapy is given.

Large doses of vitamin A are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in Table 5.7.

Re-feeding

This needs to be planned carefully. During the initial treatment of the acute situation, a balanced diet with sufficient protein and energy is given to maintain a steady state. Large increases in energy can lead to heart failure, circulatory collapse and death (*re-feeding syndrome*). Initial feeding involves administration of feeds of low osmolality and low in lactose. WHO recommendations are 100 kcal/kg per day; 1.0–1.5 g

Box 5.4 Infections seen in PEM in developing countries

9. Stimulate emotional and sensorial development				→
10. Prepare for discharge			→	

protein/kg per day and 130 mL liquid/kg per day (100 mL/kg per day if the child has marked oedema). Attempts should be made to give the feeds slowly and frequently (e.g. 2-hourly during days 1–2; 3-hourly during days 3–5; and 4-hourly thereafter), although anorexia is often a problem and can be exacerbated by excessive feeding. If necessary, fluids and food should be given by nasogastric tube. The child is then gradually weaned to liquids and then solids by mouth. All severely malnourished children have vitamin and mineral deficiencies. Although anaemia is common, the WHO recommends giving iron only after the child develops a good appetite and starts gaining weight, because of concern about making the infection worse (iron is a pro-oxidant). The child should be given daily micronutrient supplements for at least 2 weeks. These should include a multivitamin supplement with folic acid, zinc and copper.

Rehabilitation

Gradually, as the child improves, more energy can be given, and during rehabilitation weight gain is achieved by providing extra energy and protein ('catch-up weight gain'). Children who have been severely ill need constant attention right through the convalescent period, as often home conditions are poor and feeds are refused. Sensory stimulation and emotional support is a major component of management during both the stabilization and rehabilitation phases. The treatment of underlying chronic infective conditions such as HIV, malaria and tuberculosis is also necessary.

Care setting

There are not enough hospitals or therapeutic feeding centres to cope with the malnutrition problem (even acute malnutrition problems), which emphasizes the need for outpatient and community based programmes, although these require investment and time to build to full capacity. These may involve the use of ready-to-use therapeutic foods, such as energy-dense pastes with minerals and vitamins, without the need to add water, which could potentially contaminate the food.

Prognosis

Children with extreme malnutrition have a mortality of over 50%. By careful management, this can be reduced significantly to less than 10%, depending on the availability of facilities and trained staff. Treatment of underlying disease is essential. Brain development takes place in the first years of life, a time when severe PEM frequently occurs. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. Probably both of these effects can be alleviated if it is possible to maintain a high standard of living with a good diet and freedom from infection over a long period.

Prevention

Prevention of PEM depends not only on adequate nutrients being available but also on education of both governments and individuals in the importance of good nutrition and immunization (Box 5.5). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Bad feeding practices and infections are more prevalent than actual shortage of food in many areas of the world. However, good surveillance is necessary to avoid periods of famine.

Food supplements (and additional vitamins) should be given to 'at-risk' groups by adding high-energy food (e.g. milk powder, meat concentrates) to the diet. Pregnancy and lactation are times of high energy requirement and supplements have been shown to be beneficial.

Box 5.5 Prevention of protein-energy malnutrition – GOBIF (a WHO priority programme)

- Growth monitoring: The WHO has a simple growth chart that the mother keeps
- Oral rehydration, particularly for diarrhoea
- Breast-feeding supplemented by food after 6 months
- Immunization: against measles, tetanus, pertussis, diphtheria, polio and tuberculosis
- Family planning

VITAMINS

Deficiencies due to inadequate intake associated with PEM (Table 5.8) are commonly seen in the developing countries. This is not, however, invariable. For example, vitamin A deficiency is not seen in Jamaica, but is common in PEM in Hyderabad, India. In the West, deficiency of vitamins is less common but prominent in the specific groups shown in Table 5.9. The widespread use of vitamins as 'tonics' is unnecessary and should be discouraged. Toxicity from excess fat-soluble vitamins is occasionally seen.

Fat-soluble vitamins

Vitamin A

Vitamin A (retinol) is part of the family of retinoids which is present in food and the body as esters combined with long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks and fish oils. Retinol or carotene is added to margarine in the UK and other countries.

Beta-carotene is the main carotenoid found in green vegetables, carrots and other yellow and red fruits. Other carotenoids, lycopene and lutein, are probably of little quantitative importance as dietary precursors of vitamin A.

Beta-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde which can be reduced to retinol. Between a quarter and a third of dietary vitamin A in the UK is derived from retinoids. Nutritionally, 6 µg of β-carotene is equivalent to 1 µg of preformed retinol; vitamin A activity in the diet is given as retinol equivalents.

Function

Retinol is stored in the liver and is transported in plasma bound to an α-globulin, retinol-binding protein (RBP). Vitamin A has several metabolic roles:

- Retinaldehyde in its *cis* form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina (p. 1055). Light causes retinaldehyde to change to its *trans* isomer, and this leads to changes in membrane potentials that are transmitted to the brain.
- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.
- Retinyl phosphate is a cofactor in the synthesis of most glycoproteins containing mannose.

Vitamin A deficiency

Worldwide, vitamin A deficiency and xerophthalmia (see below) is the major cause of blindness in young children despite intensive preventative programmes.

Xerophthalmia has been classified by the WHO (Table 5.10). Impaired adaptation followed by night blindness is the first effect. There is dryness and thickening of the conjunctiva

Table 5.8 Fat-soluble and water-soluble vitamins: UK reference nutrient intake (RNI) and lower reference nutrient intake (LRNI) for men aged 19–50 years^a

Vitamin	RNI/day (sufficient)	LRNI/day (insufficient)	Major clinical features of deficiency	Dietary sources
Fat-soluble				
A (retinol)	700 µg	300 µg	Xerophthalmia, night blindness, keratomalacia, follicular hyperkeratosis	Oily fish, liver, dairy products (provitamin A carotenoids – carrots, dark green leafy vegetables, corn, tomatoes)
D (cholecalciferol)	No dietary intake required	10 µg (living indoors)	Rickets, osteomalacia	Oily fish, fortified breakfast cereals and margarine, eggs, milk
K	(1 µg/kg bodyweight; safe and adequate) ^b		Coagulation defects	Green leafy vegetables, liver cheese, certain fruit (kiwi fruit, rhubarb)
E (α-tocopherol)	(15 mg) ^c		Neurological disorders, e.g. ataxia	Plant oils (soya, palm oil), animal fats, nuts, seeds, vegetables, wheatgerm
Water-soluble				
B₁ (thiamin)	0.4 mg/ 1000 kcal ^d	0.23 mg/ 1000 kcal ^d	Beriberi, Wernicke–Korsakoff syndrome	Wide range of animal and vegetable products. Fortified cereals, flour, and bread, unrefined cereals, grain, nuts, legumes, organ meats
B₂ (riboflavin)	1.3 mg	0.8 mg	Angular stomatitis	Dairy products (major source) cereals grains, meat, fish, broccoli, spinach
Niacin	6.6 mg/ 1000 kcal	4.4 mg/ 1000 kcal	Pellagra	Meat, cereals
B₆ (pyridoxine)	15 µg/g of dietary protein	11 µg/g of dietary protein	Polyneuropathy	Meat, cereals
B₁₂ (cobalamin)	1.5 µg	1.0 µg	Megaloblastic anaemia, neurological disorders	Meat, fortified breakfast cereals, eggs
Folate	200 µg	100 µg	Megaloblastic anaemia	Widely distributed in animal (especially liver) and plant foods (e.g. vegetables)
C (ascorbic acid)	40 mg	10 mg	Scurvy	Fresh vegetables, citrus fruits, strawberries, spinach, tomatoes

^aValues vary with age and sex. For women, the values are generally the same or lower than for men, except during pregnancy and lactation, when they are generally higher than for men.

^bNo RNI.

^cNo official RNI in the UK because amount varies depending upon polyunsaturated fatty acid content of diet; 15 mg is the value from National Academy of Sciences USA.

^dThiamin requirements are related to energy metabolism.

Table 5.9 Some causes of vitamin deficiency in developed countries

Decreased intake
Alcohol dependency: chiefly B vitamins (e.g. thiamin)
Small bowel disease: chiefly folate, occasionally fat-soluble vitamins
Vegans: vitamin D (if no exposure to sunlight) vitamin B ₁₂ ; elderly with poor diet: chiefly vitamin D (if no exposure to sunlight), folate
Anorexia from any cause: chiefly folate
Decreased absorption
Ileal disease/resection: only vitamin B ₁₂
Liver and biliary tract disease: fat-soluble vitamins
Intestinal bacterial overgrowth: vitamin B ₁₂
Oral antibiotics: vitamin K
Miscellaneous
Long-term enteral or parenteral nutrition: usually vitamin supplements are given
Renal disease: vitamin D
Drug antagonists (e.g. methotrexate interfering with folate metabolism)

Table 5.10 Classification of xerophthalmia by ocular signs

Ocular signs	Classification
Night blindness	XN
Conjunctival xerosis	X1A
Bitot's spot	X2
Corneal xerosis	X2
Corneal ulceration/keratomalacia < ⅓ corneal surface	X3A
Corneal ulceration/keratomalacia > ⅓ corneal surface	X3B
Corneal scar	XS
Xerophthalmic fundus	XF
From WHO/UNICEF/IVACG 1988. X, xerophthalmia.	

and the cornea (xerophthalmia occurs as a result of keratinization). Bitot's spots – white plaques of keratinized epithelial cells – are found on the conjunctiva of young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration and dissolution (keratomalacia) eventually occur, superimposed infection is a frequent accompaniment and both lead to blindness. In PEM, retinol-binding protein along with other proteins is reduced. This suggests vitamin A deficiency, although body stores are not necessarily reduced.

Vitamin A in malnourished children

Vitamin A supplementation (single oral dose of 60 mg retinol palmitate) appears to improve morbidity and mortality from measles. It has also been suggested that a similar supplementation reduces morbidity and/or mortality from diarrhoeal diseases and respiratory infections and improves growth. Despite low circulating concentrations of vitamin A in HIV-infected individuals, supplementation of HIV-infected pregnant women does not appear to reduce the risk of mother-to-child transmission of HIV.

Diagnosis

In parts of the world where deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to the diagnosis is a response to replacement therapy.

Treatment

Urgent treatment with retinol palmitate 30 mg orally should be given on two successive days. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Associated malnutrition must be treated, and superadded bacterial infection should be treated with antibiotics. Referral for specialist ophthalmic treatment is necessary in severe cases.

Prevention

Most western diets contain enough dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g. margarine) in some countries. Vitamin A is not destroyed by cooking.

In some developing countries, vitamin A supplements are given at the time the child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and people should be encouraged to grow their own vegetables. In particular, pregnant women and children should be encouraged to eat green vegetables and yellow fruits.

Other effects of vitamin A

In a chronically malnourished population maternal depletions with vitamin A before, during and after pregnancy may improve lung function in the offspring at 9–13 years. It may also reduce maternal mortality. The effect of β -carotene in cardiovascular and other diseases is discussed below in the section entitled 'Dietary antioxidants' (p. 211). Retinoic acid and some synthetic retinoids are used in dermatology (p. 1213).

Possible adverse effects

- **High intakes of vitamin A.** Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, headaches and other abnormalities.

Single doses of 300 mg in adults or 100 mg in children can be harmful.

- **Retinol is teratogenic.** The incidence of birth defects in infants is high with vitamin A intakes of >3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, β -carotene is not toxic.

Vitamin D

Vitamin D is discussed in more detail in Chapter 11, where the most common manifestations of deficiency are discussed (bone and calcium disorders, Chapter 24; rickets and osteomalacia, Chapter 24). Vitamin D receptors are distributed widely in human tissues, but their function in many non-musculoskeletal tissues still remains poorly understood. Vitamin D status has been linked to a wide range of diseases, including:

- Cardiovascular (ischaemic heart disease, heart failure, hypertension)
- Respiratory (chest infections)
- Renal (progression of renal disease)
- Endocrinological (type 1 and type 2 diabetes)
- Neuropsychiatric disorders (depression, cognitive deficits)
- Cancer (e.g. prostate, breast, colon) and mortality from various causes.

It has therefore been suggested that vitamin D may have a role in global health, and not just the health of the musculoskeletal system. Studies of the relationship between vitamin D status and risk for these conditions has led to different definitions of various levels for adequate status, implying that there are different requirements for vitamin D in different diseases. However, randomized controlled trials (RCTs) of vitamin D supplementation have not been as promising in averting some of these conditions as might have been anticipated from the observational relationships.

Vitamin K

Vitamin K is found as phyloquinone (vitamin K₁) in green leafy vegetables, dairy products, rapeseed and soya bean oils. Intestinal bacteria can synthesize the other major form of vitamin K, menaquinone (vitamin K₂), in the terminal ileum and colon. Vitamin K is absorbed in a similar manner to other fat-soluble substances in the upper small gut. Some menaquinones must also be absorbed as this is the major form found in the human liver.

Function

Vitamin K is a cofactor necessary for the production not only of blood clotting factors (II, VII, IX and X, and other proteins involved in coagulation; Chapter 20), but also for proteins necessary in the formation of bone.

Vitamin K is a cofactor for the post-translational carboxylation of specific protein-bound glutamate residues in γ -carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX and X and on proteins C and S, is necessary for coagulation to take place.

Bone osteoblasts contain three vitamin K-dependent proteins, osteocalcin, matrix Gla protein and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues which bind tightly to the hydroxyapatite matrix depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing

Vitamin A deficiency.

evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

Vitamin K deficiency

Vitamin K deficiency results in inadequate synthesis of clotting factors (p. 423), which leads to an increase in the prothrombin time and haemorrhage. Deficiency occurs in the following circumstances:

The newborn

Deficiency occurs in the newborn owing to:

- poor placental transfer of vitamin K
- little vitamin K in breast milk
- no hepatic stores of menaquinone (no intestinal bacteria in the neonate).

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented by prophylactic vitamin K. Vitamin K (phytomenadione 1 mg, i.m.) is given to all neonates after risks have been discussed with parents and consent obtained.

Cholestatic jaundice

When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly. (Note that an increased prothrombin time because of liver disease does not respond to vitamin K injection, there being no shortage of vitamin K, just bad liver function.) In patients with chronic cholestasis (e.g. primary biliary cirrhosis) oral therapy using a water-soluble preparation, menadiol sodium phosphate 10 mg daily, is used.

Concomitant vitamin K antagonists

Oral anticoagulants, e.g. warfarin, antagonize vitamin K (p. 428). Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

Vitamin E

Vitamin E includes eight naturally occurring compounds divided into tocopherols and tocotrienols. The most active compound and the most widely available in food is the natural isomer d- (or RRR) α -tocopherol, which accounts for 90% of vitamin E in the human body. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals and nuts, are the main sources. Animal products are poor sources of the vitamin. Vitamin E is absorbed with fat, transported in the blood largely in low-density lipoproteins (LDL).

An individual's vitamin E requirement depends on the intake of polyunsaturated fatty acids (PUFAs). Since this varies widely, no daily requirement is given in the UK. The requirement stated in the USA is approximately 7–10 mg/day, but average diets contain much more than this. If PUFAs are taken in large amounts, more vitamin E is required.

Function

The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes, it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

Vitamin E deficiency

The first deficiency to be demonstrated was a haemolytic anaemia described in premature infants. Infant formulations now contain vitamin E.

Deficiency is seen only in children with abetalipoproteinemia (p. 270) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented by vitamin E injections.

Plasma or serum levels of α -tocopherol can be measured and should be corrected for the level of plasma lipids by expressing the value as milligrams per milligram of plasma lipid.

Epidemiological data and clinical trials

Animals fed an atherogenic diet supplemented with α -tocopherol develop many fewer new atheromatous lesions than those fed an atherogenic diet alone; there may be regression of existing lesions.

There is also evidence for vitamin E intake and blood α -tocopherol levels as an independent risk factor for the development of ischaemic heart disease (IHD) in healthy, well-nourished individuals eating a western diet. This has been shown in comparisons of different communities in the WHO 'MONICA' observational study.

Randomized trials involving vitamin E supplementation have produced conflicting results, possibly due to factors such as short duration of treatment, use of suboptimal doses or without the concurrent administration of vitamin C. There are very few trials to assess the role of vitamin E in prevention of peripheral vascular disease and for cancer prevention.

Water-soluble vitamins

Water-soluble vitamins are non-toxic and relatively cheap and can therefore be given in large amounts if a deficiency is possible. The daily requirements of water-soluble vitamins are given in Table 5.8.

Thiamin (vitamin B₁)

Function

Thiamin diphosphate, often called thiamin pyrophosphate (TPP), is an essential cofactor, particularly in carbohydrate metabolism.

TPP is involved in the oxidative decarboxylation of acetyl CoA in mitochondria. In formation of acetyl CoA (from pyruvate) and in the Krebs cycle, TPP is the key enzyme for the decarboxylation of α -ketoglutarate to succinyl CoA. TPP is also the cofactor for transketolase, a key enzyme in the hexose monophosphate shunt.

Thiamin is found in many foodstuffs, including cereals, grains, beans, nuts, as well as pork and duck. It is often added to food (e.g. in cereals) in developed countries. The dietary requirement (see Table 5.8) depends on energy intake, more being required if the diet is high in carbohydrates.

Following absorption, thiamin is found in all body tissues, the majority being in the liver. Body stores are small and signs of deficiency quickly develop with inadequate intake.

There is no evidence that a high oral intake is dangerous, but ataxia has been reported after high parenteral therapy.

Thiamin deficiency

Thiamin deficiency is seen:

- as **beriberi**, where the only food consumed is polished rice
- in **chronic alcohol-dependent patients** who are consuming virtually no food at all

- in **starved patients** (e.g. with carcinoma of the stomach), and in severe prolonged hyperemesis gravidarum, anorexia nervosa and prolonged total starvation in healthy subjects (e.g. fasts for political reasons). It can also occur in patients given parenteral nutrition with little or no thiamine as large doses of glucose increase requirements of thiamin and can precipitate deficiency, e.g. during re-feeding.

Beriberi

This is now confined to the poorest areas of South-east Asia. It can be prevented by eating undermilled or par-boiled rice, or by fortification of rice with thiamine. The prevention of beriberi needs a general increase in overall food consumption so that the staple diet is varied and contains legumes and pulses, which contain a large amount of thiamin. There are two main clinical types of beriberi which, surprisingly, only rarely occur together.

- **Dry beriberi** usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually all the signs of polyneuropathy that may involve the trunk and arms are found (p. 1147). Cerebral involvement occurs, producing the picture of the Wernicke–Korsakoff syndrome (p. 1147). In endemic areas, mild symptoms and signs may be present for years without unduly affecting the patient.
- **Wet beriberi** causes oedema. Initially this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi.

Thiamin deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially there are warm extremities, a full, fast, bounding pulse and a raised venous pressure ('high-output state'), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

Infantile beriberi occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamin deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema and has some degree of aphonia. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

Diagnosis

In endemic areas, the diagnosis of beriberi should always be suspected and if in doubt treatment with thiamine should be instituted. A rapid disappearance of oedema after thiamine (50 mg i.m.) is diagnostic. Other causes of oedema must be considered (e.g. renal or liver disease), and the polyneuropathy is indistinguishable from that due to other causes. The diagnosis is confirmed by measurement of the circulating thiamin concentration or transketolase activity in red cells using fresh heparinized blood.

Treatment

Thiamine 50 mg i.m. is given for 3 days, followed by 50 mg of thiamine daily by mouth. The response in wet beriberi occurs in hours, giving dramatic improvement, but in dry beriberi improvement is often slow to occur. In most cases

all the B vitamins are given because of multiple deficiency. Infantile beriberi is treated by giving thiamine to the mother, which is then passed on to the infant via the breast milk.

Thiamin deficiency in people with alcohol dependence or acute illness

In the developed world, alcohol-dependent people and those with severe acute illness receiving high-carbohydrate infusions without vitamins are the only major groups to suffer from thiamin deficiency. Rarely, they develop wet beriberi, which must be distinguished from alcoholic cardiomyopathy. More usually, however, thiamin deficiency presents with polyneuropathy or with the Wernicke–Korsakoff syndrome.

This syndrome, which consists of dementia, ataxia, varying ophthalmoplegia and nystagmus (see p. 1147), presents acutely and should be suspected in all heavy drinkers. If treated promptly it is reversible; if left it becomes irreversible. It is a major cause of dementia in the USA.

Urgent treatment with thiamine 250 mg i.m. or i.v. infusion once daily is given for 3 days, often combined with other B-complex vitamins. Anaphylaxis can occur. Thiamine must always be given before any intravenous glucose infusion.

Riboflavin

Riboflavin is widely distributed throughout all plant and animal cells. Good sources are dairy products, offal and leafy vegetables. Riboflavin is not destroyed appreciably by cooking, but is destroyed by sunlight. Riboflavin is a flavo-protein that is a cofactor for many oxidative reactions in the cell.

There is no definite deficiency, although many communities have low dietary intakes. Studies in volunteers taking a low riboflavin diet have produced:

- angular stomatitis or cheilosis (fissuring at the corners of the mouth)
- a red, inflamed tongue
- seborrhoeic dermatitis, particularly involving the face (around the nose) and the scrotum or vulva.

Conjunctivitis with vascularization of the cornea and opacity of the lens has also been described. It is probable, however, that many of the above features are due to multiple deficiencies rather than the riboflavin itself.

Riboflavin 5 mg daily can be tried for the above conditions, usually given as the vitamin B complex.

Niacin

This is the generic name for the two chemical forms, nicotinic acid and nicotinamide, the latter being found in the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both act as hydrogen acceptors in many oxidative reactions, and in their reduced forms (NADH and NADPH) act as hydrogen donors in reductive reactions. Many oxidative steps in the production of energy require NAD, and NADP.

Niacin is found in many foodstuffs, including plants, meat (particularly offal) and fish. Niacin is lost by removing bran from cereals but is added to processed cereals and white bread in many countries.

Niacin can be synthesized in humans from tryptophan, 60 mg of tryptophan being converted to 1 mg of niacin. The amount of niacin in food is given as the 'niacin equivalent', which is equal to the amount of niacin plus one-60th of the tryptophan content. Eggs and cheese contain tryptophan.

Kynureninase and kynurenine hydroxylase, key enzymes in the conversion of tryptophan to nicotinic acid, are both B₆

a

Scurvy. Corkscrew hairs and perifollicular haemorrhage on the lower extremities. (From: Bologna J, Jorizzo J, Rapini R (eds). *Dermatology*, 2nd edn. St Louis: Mosby; 2008: Fig. 51.8A, with permission.)

and riboflavin dependent, and deficiency of these B vitamins can also produce pellagra.

Pellagra

This is rare and is found in people who eat virtually only maize, for example in parts of Africa. Maize contains niacin in the form of niacytin, which is biologically unavailable, and has a low content of tryptophan. In Central America, pellagra has always been rare because maize (for the cooking of tortillas) is soaked overnight in calcium hydroxide, which releases niacin. Many of the features of pellagra can be explained purely by niacin deficiency; but some are probably due to multiple deficiencies, including deficiencies of proteins and of other vitamins.

Clinical features

The classical features are of dermatitis, diarrhoea and dementia. Although this is an easily remembered triad, not all features are always present and the mental changes are not a true dementia.

- **Dermatitis.** In the areas of skin exposed to sunlight, initially there is redness followed by cracks with occasional ulceration. Chronic thickening, dryness and pigmentation develop. The lesions are always symmetrical and often affect the dorsal surfaces of the hands. The perianal skin and vulva are frequently involved. Casal's necklace or collar is the term given to the skin lesion around the neck, which is confined to this area by the clothes worn.
- **Diarrhoea.** This is often a feature but constipation is occasionally seen. Other gastrointestinal manifestations include a painful, red, raw tongue, glossitis and angular stomatitis. Recurring mouth infections occur.
- **Dementia.** This occurs in chronic disease. In milder cases there are symptoms of depression, apathy and sometimes thought disorders. Tremor and an encephalopathy frequently occur. Hallucinations and acute psychosis are also seen with more severe cases. Pellagra may also occur in the following circumstances:
 - Isoniazid therapy can lead to a deficiency of vitamin B₆, which is needed for the synthesis of nicotinamide from tryptophan. Vitamin B₆ is now given concomitantly with isoniazid.
 - In Hartnup's disease, a rare inborn error, in which basic amino acids including tryptophan are not absorbed by the gut. There is also loss of this amino acid in the urine.
 - In generalized malabsorption (rare).
 - In alcohol-dependent patients who eat little.
 - Very low protein diets given for renal disease or taken as a food fad.
 - In the carcinoid syndrome and pheochromocytomas, tryptophan metabolism is diverted away from the formation of nicotinamide to form amines.

Diagnosis and treatment

In endemic areas, this is based on the clinical features, remembering that other vitamin deficiencies can produce similar changes (e.g. angular stomatitis). Nicotinamide (approximately 300 mg daily by mouth), with a maintenance dose of 50 mg daily is given with dramatic improvement in the skin and diarrhoea. Mostly, however, vitamin B complex is given, as other deficiencies are often present.

An increase in the protein content of the diet and treatment of malnutrition and other vitamin deficiencies is essential.

Vitamin B₆

Vitamin B₆ exists as pyridoxine, pyridoxal and pyridoxamine, and is found widely in plant and animal foodstuffs. Pyridoxal phosphate is a cofactor in the metabolism of many amino acids. Dietary deficiency is extremely rare. Some drugs (e.g. isoniazid, hydralazine and penicillamine) interact with pyridoxal phosphate, producing B₆ deficiency. The polyneuropathy occurring after isoniazid usually responds to vitamin B₆.

Sideroblastic anaemia may respond to vitamin B₆ (see p. 380).

A polyneuropathy has occurred after high doses (>200 mg) given over many months. Vitamin B₆ is used for premenstrual tension: a daily dose of 10 mg should not be exceeded.

Biotin and pantothenic acid

Biotin is involved in a number of carboxylase reactions. It occurs in many foodstuffs and the dietary requirement is small. Deficiency is extremely rare and is confined to a few people who consume raw eggs, which contain an antagonist (avidin) to biotin. It has also been reported in patients receiving long-term parenteral nutrition without adequate amounts of biotin. It causes a dermatitis that responds to biotin replacements.

Pantothenic acid is widely distributed in all foods and deficiency in humans has not been described.

Vitamin C

Ascorbic acid is a powerful reducing agent controlling the redox potential within cells. It is involved in the hydroxylation of proline to hydroxyproline, which is necessary for the formation of collagen. The failure of this biochemical pathway in vitamin C deficiency accounts for virtually all of the clinical effects seen.

Humans, along with a few other animals (e.g. primates and the guinea-pig), are unusual in not being able to synthesize ascorbic acid from glucose.

Vitamin C is present in all fresh fruit and vegetables. Unfortunately, ascorbic acid is easily leached out of vegetables when they are placed in water and it is also oxidized to dehydro-ascorbic acid during cooking or exposure to copper or alkalis. Potatoes are a good source as many people eat a lot of them, but vitamin C is lost during storage.

It has been suggested that ascorbic acid in high dosage (1–2 g daily) will prevent the common cold. While there is some scientific support for this, clinical trials have shown no significant effect. Vitamin C supplements have also been advocated to prevent atherosclerosis and cancer, but again a clear benefit has not been demonstrated.

Vitamin C deficiency is seen mainly in infants fed boiled milk and in the elderly and single people who do not eat vegetables. In the UK, it is also seen in Asians eating only rice and chapattis and in food faddists.

Scurvy

In adults, the early symptoms of vitamin C deficiency may be nonspecific, with weakness and muscle pain. Other features are shown in Table 5.11. Parafollicular haemorrhages and corkscrew hairs occur. In infantile scurvy, there is irritability, painful legs, anaemia and characteristic subperiosteal haemorrhages, particularly into the ends of long bones.

Diagnosis

The anaemia is usually hypochromic but occasionally, a normochromic or megaloblastic anaemia is seen. The type of anaemia depends on whether iron deficiency (owing to

Table 5.11 Clinical features of vitamin C deficiency (scurvy)

Keratosis of hair follicles with 'corkscrew' hair
 Perifollicular haemorrhages
 Swollen, spongy gums with bleeding and superadded infection, loosening of teeth
 Spontaneous bruising
 Spontaneous haemorrhage
 Anaemia
 Failure of wound healing

decreased absorption or loss due to haemorrhage) or folate deficiency (folate being largely found in green vegetables) is present.

Plasma ascorbic acid is very low in obvious deficiency and a vitamin C level of $<11 \mu\text{mol/L}$ ($0.2 \text{ mg}/100 \text{ mL}$) indicates vitamin C deficiency. The leucocyte-platelet layer (buffy coat) of centrifuged blood corresponds to vitamin C concentrations in other tissues. The normal level of leucocyte ascorbate is $1.1\text{--}2.8 \text{ pmol}/10^6$ cells.

Treatment

Initially the patient is given 250 mg of ascorbic acid daily and encouraged to eat fresh fruit and vegetables. Subsequently, 40 mg daily will maintain a normal exchangeable body pool of about 900 mg (5.1 mmol).

Prevention

Orange juice should be given to bottle-fed infants. The intake of breast-fed infants depends on the mother's diet. In the elderly, eating adequate fruit and vegetables is the best way to avoid scurvy. Careful surveillance of the elderly, particularly those who live alone, is necessary. Ascorbic acid supplements should only be necessary occasionally.

Vitamin B₁₂ and folate

These are dealt with on page 381 and daily requirements are shown in Table 5.8.

Folate. In many developed countries, up to 15% of the population have a partial deficiency of 5,10-methylene tetrahydrofolate reductase, a key folate-metabolizing enzyme. This is due to a point mutation and is associated with an increase in neural tube defects and hyperhomocysteinaemia, which has been linked to cardiovascular disease. Autoantibodies against folate receptors have been found in serum from women who have had a pregnancy complicated by neural tube defects. However, the role of this in the pathogenesis is unclear.

In the USA and some other countries, enriched cereals are fortified with 1.4 mg/kg grain of folic acid to increase daily requirements.

Dietary antioxidants

Free radicals are generated during inflammatory processes, radiotherapy, smoking, and during the course of a wide range of diseases. They may cause uncontrolled damage of multiple cellular components, the most sensitive of which are unsaturated lipids, proteins and DNA, and they also disrupt the normal replication process. They have been implicated as a cause of a wide range of diseases, including malignant, acute inflammatory and traumatic diseases, cardiovascular disease, neurodegenerative conditions such as Alzheimer's disease, senile macular degeneration, and cataract. The defence against uncontrolled damage by free

radicals is provided by antioxidant enzymes (e.g. catalase, superoxide dismutase) and antioxidants, which may be endogenous (e.g. glutathione) or exogenous (e.g. vitamins C and E, carotenoids). A possible causal link between lack of antioxidants and cardiovascular disease has emerged from epidemiological studies although several RCTs have not confirmed this.

Epidemiological studies

Dietary intake

- A high intake of fruits and vegetables has been linked to reduced risk of heart disease, cerebrovascular disease and total cardiovascular morbidity and mortality.
- A high intake of nuts (rich in vitamin E) and dietary components, e.g. red wine, onions, apples (rich in flavonoids), which are strong scavengers of free radicals, has also been linked to reduced risk of cardiovascular disease.
- The seasonal variation in cardiovascular disease, which is higher in winter, has been related to decreased intake of fresh fruit and vegetables in winter.
- The decline in cardiovascular disease in the USA since the 1950s has been associated with a simultaneous increase in the intake of fresh fruit and vegetables.

Status of antioxidant nutrients

The level of antioxidant nutrients in the circulation has been reported to be inversely related to cardiovascular morbidity and mortality, extent of atherosclerosis assessed by intra-arterial ultrasound, and clinical signs of ischaemic heart disease. The tissue content of lycopene, a marker of vegetable intake, has been reported to be low in patients with myocardial infarction.

Antioxidants, especially vitamin E, have been shown to prevent the initiation and progression of atherosclerotic disease in animals. They also reduce the oxidation of low-density lipoprotein (LDL) in the arterial wall *in vitro*. Oxidation of LDL is an initial event in the atherosclerotic process (p. 725). However, these epidemiological studies show an association rather than a causal link and RCTs comparing the antioxidant against a control group are necessary.

Randomized controlled trials (RCT) (see also p. 905). The results of such trials have been formally evaluated through a series of systematic reviews and meta-analyses.

- **For primary or secondary prevention** of cardiovascular disease, intervention with β -carotene, α -tocopherol (vitamin E) and ascorbic acid (vitamin C) has demonstrated no significant benefit.
- Vitamin E or β -carotene given in, e.g. stroke and fatal and non-fatal myocardial infarction, has also not yielded benefits.
- There is a report of increased risk of intracerebral and subarachnoid haemorrhage in healthy individuals receiving carotene and α -tocopherol.
- A meta-analysis has shown a small but significant overall increased risk of cardiovascular death and all-cause mortality in individuals treated with β -carotene (compared to the control group).
- An increased risk of developing lung cancer by administering large doses of β -carotene to subjects with a history of heavy smoking.
- Although administration of antioxidant nutrients has been proposed in a wide range of acute (e.g. critical illness, pancreatitis) and chronic diseases, the evidence base from RCTs is generally not strong.

- In some cases, improvement in indices of free radical damage had been demonstrated (e.g. in acute inflammatory conditions), but with little evidence of clinical benefit.

Epidemiological studies are also confounded by other associated variables, e.g. eating a low-fat diet or undertaking more exercise. The latter may be more valuable in the causal pathway than the intake of antioxidants. Diets rich in fresh fruit and vegetables also contain a range of antioxidants that were not tested in the clinical trials. Therefore, the results of large-scale RCTs using various combinations and doses of antioxidant nutrients are awaited. In the meantime, the policy of encouraging 'healthy' behaviour, which includes increased physical activity and a varied diet rich in fresh fruit and vegetables, and nuts, is still generally recommended both for the population as a whole and for those at risk of cardiovascular disease.

Homocysteine, cardiovascular disease and B vitamins

The circulating concentration of the amino acid homocysteine is an independent risk factor for cardiovascular disease (p. 728). A high concentration is related to ischaemic heart disease, stroke, thrombosis, pulmonary embolism, coronary artery stenosis, and heart failure. The strength of the association is similar to smoking or hyperlipidaemia.

Proposed mechanisms, based on experimental evidence, by which homocysteine detrimentally affects vascular function, include:

- the direct damaging effects of homocysteine on endothelial cells of blood vessels
- an increase in blood vessel stiffness
- an increase in blood coagulation.

Homocysteine is not found in food, but results from metabolism within the body which depends on folic acid, vitamin B₁₂ and pyridoxine (vitamin B₆) (Fig. 5.7). Deficiency of one or more of these vitamins is common in the elderly, which would increase the concentration of homocysteine. If an elevated homocysteine concentration was causally linked to

cardiovascular disease then it should be possible to lower the risk by administering one or more of these vitamins to lower the homocysteine concentration. However, several recent studies suggest that lowering homocysteine concentrations in this way does not reduce the risk of cardiovascular disease.

MINERALS

A number of minerals have been shown to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable that trace-element deficiency is also a frequent accompaniment of all PEM states, but this is difficult to study because of multiple deficiencies. Sodium, potassium, magnesium and chloride are discussed in Chapter 13. Reference nutrient intake (RNI) values are shown in Table 5.12.

Iron

Iron deficiency (see also p. 379) is common worldwide, affecting both developing and developed countries. It is

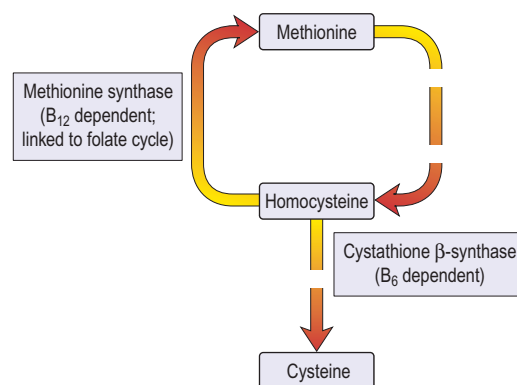

Figure 5.7 Homocysteine metabolism.

Table 5.12 Daily reference nutrient intake (RNI) values for some elements

Element	Daily RNI	Dietary sources
Sodium	1.6 g (70 mmol)	Mostly in processed food (e.g. meat products, bread cereal) but added salt contributes
Chloride	2.5 g (70 mmol)	As for sodium
Potassium	3.5 g (90 mmol)	Vegetables, fruit, juices, meat and milk
Calcium	700 mg (17.5 mmol) ^a	In many foodstuffs; two-thirds of intake comes from milk and milk products, and only 5% from vegetables ^b
Phosphate	550 mg (17.5 mmol)	All natural foods e.g. milk, meat, bread, cereals,
Magnesium	300 mg (12.3 mmol) for men 270 mg (10.9 mmol) for women	Milk bread, cereal products, potatoes and other vegetables
Iron	160 µmol (8.7 mg) for men 260 µmol (14.8 mg) for women	Meat, bread, flour, cereal products, potatoes and vegetables
Copper	1.2 mg (19 µmol)	Shellfish, legumes, cereals and nuts
Zinc	9.5 mg (145 µmol) for men 7 mg (110 µmol) for women	Widely available in food
Iodine	140 µg (1.1 µmol)	Milk, meat and seafoods
Fluoride	None	Little fluoride in food except seafood and tea (tea provides 70% of daily intake)
Selenium	75 µg (0.9 µmol) for men 60 µg (0.8 µmol) for women	Cereals, fish, meat, cheese, eggs, milk

^aUK value; a substantially higher value is recommended in the USA.
^bIn the UK, most flour is fortified.

particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

Copper

Deficiency

Menkes' kinky hair syndrome is a rare condition caused by malabsorption of copper. The Menkes' disease gene (*ATP7A*) encodes a copper-transporting ATPase and has a homology to the gene in Wilson's disease. Infants with this sex-linked recessive abnormality develop growth failure, mental retardation, bone lesions and brittle hair. Anaemia and neutropenia also occur. This condition, which serves as a model for copper deficiency, supports the idea that some of the clinical features seen in PEM are due to copper deficiency. Breast and cow's milk are low in copper, and supplementation is occasionally necessary when first treating PEM.

Copper toxicity

This occurs in Wilson's disease; see page 315.

Zinc

Zinc is involved in many metabolic pathways, often acting as a coenzyme; it is essential for the synthesis of RNA and DNA.

Deficiency

Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss and a skin rash, which can occur anywhere on the body, but most often around the mouth, genitalia and hands (a similar rash occurs in adults suffering from zinc deficiency due to other causes (see below). There are also associated *Candida* and bacterial infections. This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Zinc deficiency probably also plays a role in PEM and in many diseases in children in the developing world. Zinc supplementation has been shown to be of some benefit in, for example, the prevention of diarrhoeal diseases and acute respiratory infections; it also improves growth.

Zinc levels have also been shown to be low in some patients with malabsorption or skin disease, and in patients with AIDS, but the exact role of zinc in these situations is disputed. Zinc has low toxicity, but high zinc levels from water stored in galvanized containers interfere with iron and copper absorption. Conversely, administration of copper or iron to treat deficiencies such as iron deficiency anaemia can precipitate zinc deficiency. Wound healing is impaired with moderate zinc deficiency and is improved by zinc supplements. Impaired taste and smell, hair loss and night blindness are also features of severe zinc deficiency.

Iodine

Iodine exists in foodstuffs as inorganic iodides which are efficiently absorbed. Iodine is a constituent of the thyroid hormones (p. 960).

Deficiency

Many areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Two billion people (one-third children) worldwide have insufficient iodine intake. Endemic goitre occurs in remote areas where the daily intake is below 70 µg, and in those parts 1–5% of babies are born with cretinism. In

Table 5.13 Other trace elements (see text)

Element	Deficiency
Cadmium	?
Chromium	Glucose intolerance
Cobalt	Anaemia (vitamin B ₁₂)
Manganese	Skin rash, ? osteoporosis, ? mood
Molybdenum	? (case study involving parenteral nutrition)
Nickel	? Animals only
Vanadium	?

these areas, iodized oil should be given intramuscularly to all reproductive women every 3–5 years. Salt iodization is now used in many countries and is a simple, cost-effective way to prevent deficiency.

Fluoride

In areas where the level of fluoride in drinking water is less than 1 p.p.m. (0.7–1.2 mg/L), dental caries is relatively more prevalent. Fluoridation of the water provides 1–2 mg daily, resulting in a reduction of about 50% of tooth decay in children. There is little fluoride in food. Fluoride-containing toothpaste may add up to 2 mg/day.

Excessive fluoride intake in areas where the water fluoride level is above 3 mg/L can result in fluorosis, in which there is infiltration into the enamel of the teeth, producing pitting and discoloration.

Selenium

Clinical deficiency of selenium is rare except in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Selenium deficiency may also cause a myopathy. Toxicity has been described with very high intakes.

Calcium

Calcium absorption (see also p. 513) from the gastrointestinal tract is vitamin D-dependent. Some 99% of body calcium is in the skeleton.

Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

Phosphate

Phosphates (see also p. 519) are present in all natural foods, and dietary deficiency has not been described. Patients taking large amounts of aluminium hydroxide can, however, develop phosphate deficiency owing to binding in the gut lumen. It can also be seen in total parenteral nutrition. Symptoms include anorexia, weakness and osteoporosis.

Other trace elements

The possible significance of cadmium, chromium, cobalt, manganese, molybdenum, nickel and vanadium is shown in Table 5.13.

NUTRITION AND AGEING

Many animal studies have shown that life expectancy can be extended by restricting food intake. It is, however, not known

whether the ageing process in humans can be altered by nutrition.

The ageing process

The process of ageing is not well understood. While wear and tear may play a role, it is an insufficient explanation for the causation of ageing. The 'programmed' theories depend on inbuilt biological clocks that regulate lifespan, and involve genes that are responsible for controlling signals that influence various body systems. The 'error' theories involve environmental stressors that induce damage (e.g. mitochondrial DNA damage or cross-linking).

The search for a single cause of ageing, e.g. a single gene defect, has been replaced by the view that ageing is a complex multifactorial process that involves an interaction between genetic, environmental and stochastic (random damage to essential molecules) causes. The following theories have been suggested:

Molecular theories

- **Gene regulation:** ageing, for example, results from changes in expression of genes that regulate both development and ageing. An insulin-like signalling pathway has been linked to the lifespan of worms, flies and mice (activation of a transcription factor in response to reduced insulin-like signalling prolongs lifespan)
- **Codon restriction:** inadequate mRNA translation resulting from inadequate decoding of codons in mRNA
- **Error catastrophe:** errors in gene expression result in abnormal proteins
- **Somatic mutation:** cumulative molecular damage mainly to genetic material
- **Dysdifferentiation:** cumulative random molecular damage detrimentally affects gene expression.

Mutations in genes encoding lamin A are found in fibroblasts of elderly people and in progeria syndromes.

Cellular theories

- **Cellular senescence-telomere:** an increase in senescent cells occurs from:
 - *Loss of telomeres*, which is known to occur with ageing (with each cell division a small amount of DNA is necessarily lost at each end of the chromosome). Activation of the telomerase enzyme regenerates telomeres, prevents senescence (replicative senescence) and immortalizes cell cultures. Cancer cells are known to activate telomerase. Accelerated telomerase shortening occurs in progerias, such as Werner's syndrome. One study has also found that telomere length in leucocytes predicts coronary artery disease in middle-aged men at high risk and these individuals might benefit from statin treatment.
 - *Damage* due to a variety of other factors, including DNA damage (stress-induced senescence).
- **Free radical:** production of free radicals during oxidative metabolism, which damages fat, protein and DNA.
- **Wear and tear:** cumulative damage from normal injury/stress which is unable to repair itself.
- **Apoptosis theory:** programmed cell death due to genetic events.

System theories

These theories involve loss in the function of neuroendocrine or immune systems with consequent age-related physiological changes and an increase in autoimmunity.

Whole body metabolism and energy expenditure theory proposes that there is a fixed limit to the cumulative energy expenditure and metabolism during a lifetime, so that if this limit is reached quickly the lifespan is short. Energy restriction in rodents reduces energy expenditure and prolongs lifespan, but there is a lack of studies in primates or humans.

Evolutionary theories

- **Cumulative mutation:** mutations that accumulate during a lifetime act in older age rather than during the active reproductive period (for which there is evolutionary selection), producing pathology and senescence. The theory was initially based on the observation that Huntington's disease, a dominant lethal mutation which typically manifests itself between 35 and 55 years, allows affected individuals to reproduce.
- **Disposable soma:** the somatic body is maintained to ensure reproductive success, after which it is disposable. Factors that may enhance reproductive success may have detrimental effects on ageing – a possible example being androgen secretion, which may be beneficial to reproduction but potentially detrimental with development of prostatic cancer and cardiovascular disease in later life.

Nutritional components of theories of ageing

Several of the theories above have strong nutritional components. *Disability and dependency* in older humans are at least partly due to poor nutrition, and correction of deficiencies or nutrient imbalances can prevent the decline in function from falling below the disability threshold (Fig. 5.8). In this way, some loss of function may be prevented or reversed, especially if other measures, such as physical activity, which increases muscle mass and strength, are undertaken.

Early origins of health and disease in older adults

A low birth weight (and/or length) is associated with reduced height, as well as reduced mass and fat-free mass in adult life. These relationships are independent of genetic factors: the smaller of identical twins becomes a shorter and lighter adult.

Relationships have also been reported between growth of the fetus and a variety of diseases and risk factors for disease in adults and older people. These include cardiovascular disease (especially ischaemic heart disease), hypertension and diabetes, and even obesity and fat distribution. However, the strength of association for some of these conditions is weak. Animal studies involving dietary modifications (e.g. protein and zinc, even within the normal range) during pregnancy or in early postnatal life have clearly demonstrated effects, such as hypertension. The effects can persist, not only through the lifetime of the offspring, but also through to their offspring.

The extent to which these findings apply to humans is uncertain, and the mechanisms are poorly understood. Since relationships have been reported between cardiovascular disease in old age and growth in the first few years of life, as well as starvation during puberty, it is likely that cumulative environmental stresses, including nutritional stress, from the time of implantation of the fertilized egg, to fetal and postnatal growth and development, and into adult life, summate to produce an overall disease risk (Fig. 5.8).

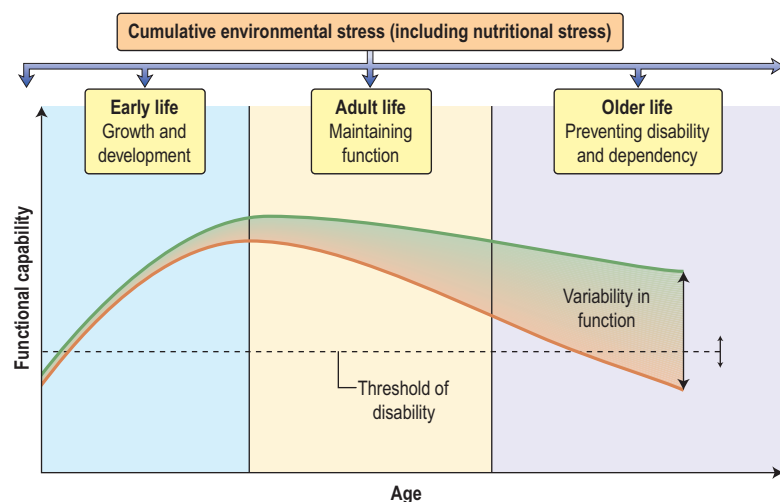

Figure 5.8 Nutrition and ageing.

Nutrition is a contributory cause of the variability in function during the lifespan. Appropriate nutrition may improve function, or delay deterioration below the threshold of disability and dependence.

Nutritional requirements in the elderly

These are qualitatively similar to the requirements of younger adults: the diet should contain approximately the same proportions of nutrients, and essential nutrients are still required. However, the RNI's stated earlier (p. 195) are intended for healthy people without disease; specific requirements in disease, which is common in older people, are less well-defined.

Maintenance of physical activity continues to be necessary for overall health, regardless of age. However, energy expenditure by the elderly is less, so they have a lower energy requirement. For people aged 60 and above, irrespective of age, the daily energy requirement has been set to be approximately $1.5 \times \text{BMR}$. Because they have reduced fat-free mass, from an average of 60 kg to 50 kg in men and from 40 kg to 35 kg in women, their BMR is reduced.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, lack of cooking skills (particularly in widowers), depression and lack of motivation. Significant malnourishment in developed countries is usually secondary to social problems or disease. In elderly people who are in institutions, multiple nutrient deficiencies are common. Vitamin D supplements may be required because often elderly people do not go into the sunlight. Owing to the high prevalence of osteoporosis in elderly people, increased daily calcium intake ($1\text{--}1.5 \text{ g/day}$) is often recommended.

OBESITY

Obesity is almost invariable in developed countries and almost all people accumulate some fat as they get older. The World Health Organization acknowledges that obesity ($\text{BMI} > 30 \text{ kg/m}^2$) is a worldwide problem which also affects many developing countries. Obesity implies an excess storage of fat, and this can most easily be detected by looking at the undressed patient. Not all obese people eat more than the average person, but all obviously eat more than they need.

The present obesity epidemic is mainly due to changes in lifestyle behaviour (although genetic factors may be involved in some individuals). There has been a trebling in the prevalence of obesity in the UK over the last three decades as well as a vast increase in developing countries. The growing obesity problem in humans has affected children, adults and

Table 5.14 Conditions in which obesity is an associated feature

Genetic syndromes associated with hypogonadism (e.g. Prader-Willi syndrome, Laurence-Moon-Biedl syndrome)
Hypothyroidism
Cushing's syndrome
Stein-Leventhal syndrome
Drug-induced (e.g. corticosteroids)
Hypothalamic damage (e.g. due to trauma, tumour)

older people. Clinical and public health interventions require a multi-level approach, e.g. by altering the cumulative environmental experience during the lifespan. Strategies to prevent and treat obesity in children can influence obesity in adults, and this in turn influences obesity in old age. Ultimately, all depend on changing energy balance through effects on food intake and/or energy expenditure.

Most patients suffer from simple obesity, but in certain conditions, obesity is an associated feature (Table 5.14). Even in the latter situation, the intake of calories must have exceeded energy expenditure over a prolonged period of time. Hormonal imbalance is often incriminated in women (e.g. postmenopause or when taking contraceptive pills), but most weight gain in such cases is usually small and due to water retention.

Suggested mechanisms

Genetic and environmental factors

These have always been difficult to separate when studying obesity, but there is little doubt that the recent obesity 'epidemic', which has developed over a few decades, is predominantly due to changes in lifestyle (various environmental factors) and unlikely to be due to rapid changes in the gene pool over this period of time. This is consistent with the view that evolution during times of limited food resources has tended to defend more against undernutrition than overnutrition. However, observational studies in both monozygotic and dizygotic twins, reared together or apart, suggest that strong genetic influences account for the difference in BMI later in life, and that the influence of the childhood environment is weaker. These observations also showed that weight gain did not occur in all pairs of twins, suggesting that environmental factors operate.

A search for genetic factors led to the identification of a putative gene, first in the obese (*ob ob*) mouse and now in

humans. The *ob* gene was shown to be expressed solely in both white and brown adipose tissue. The *ob* gene is found on chromosome 7 and produces a 16 kDa protein called leptin. In the *ob ob* mouse, a mutation in the *ob* gene leads to production of a non-functioning protein. Administration of normal leptin to these obese mice reduces food intake and corrects the obesity. A similar situation has been described in a very rare genetic condition causing obesity in humans, in which leptin is not expressed.

In massively obese subjects, leptin mRNA in subcutaneous adipose tissue is 80% higher than in controls. Plasma levels of leptin are also very high, correlating with the BMI. Weight loss due to food restriction decreases plasma levels of leptin. However, in contrast to the *ob ob* mouse, the leptin structure is normal, and abnormalities in leptin are not the prime cause of human obesity.

Leptin secreted from fat cells was thought to act as a feedback mechanism between the adipose tissue and the brain, acting as a 'lipostat' (adipostat), controlling fat stores by regulating hunger and satiety (see below). However, many other signals are involved and the human genome map has identified hundreds of genes that correlate with the presence of obesity. It is also interesting that obesity is largely restricted to humans and animals that are either domesticated or in zoos.

Food intake

Many factors related to the home environment, such as finance and the availability of sweets and snacks, will affect

food intake. Some individuals eat more during periods of heavy exercise or during pregnancy and are unable to get back to their former eating habits. The increase in obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). Psychological factors and how food is presented may override complex biochemical interactions.

It has been shown that obese patients eat more than they admit to eating, and over the years, a very small daily excess of intake over expenditure can lead to a large accumulation of fat. For example, a 44 kJ (10.5 kcal) daily excess would lead to a 10 kg weight gain over 20 years.

Control of appetite

Appetite is the desire to eat and this usually initiates food intake. Following a meal, satiation occurs. This depends on gastric and duodenal distension and the release of many substances peripherally and centrally.

Following a meal, cholecystokinin (CCK), bombesin, glucagon-like peptide 1 (GLP-1), enterostatin, and somatostatin are released from the small intestine, and glucagon and insulin from the pancreas. All of these hormones have been implicated in the control of satiety. Centrally, the hypothalamus – particularly the lateral hypothalamic area, and paraventricular and arcuate nuclei – plays a key role in integrating signals involved in appetite and bodyweight regulation (Fig. 5.9). There are two main pathways in the arcuate nucleus (Fig. 5.9):

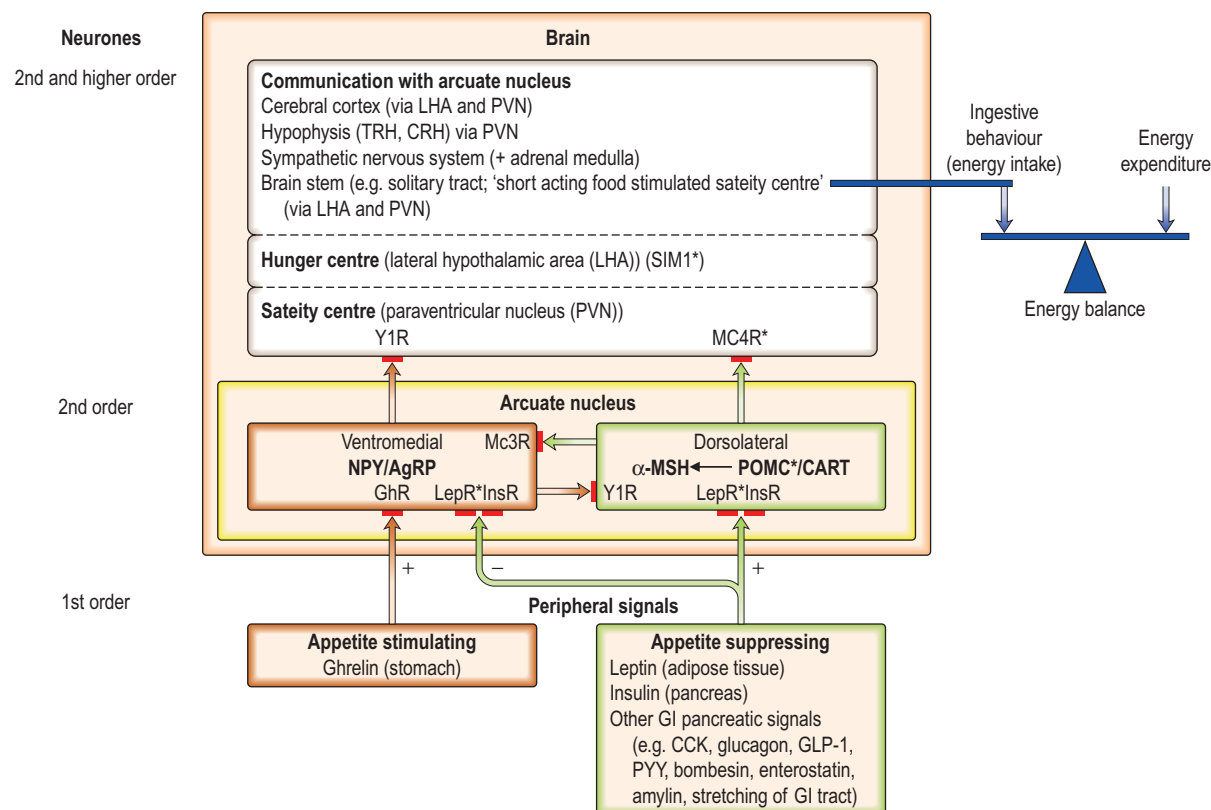

Figure 5.9 Peripheral signals and central pathways involved in the control of food intake. The stimulatory (orange) and suppressive (green) signals and pathways are shown. In the arcuate nucleus POMC is converted to melanocortins, including α -MSH, through the action of prohormone convertase. The solid red areas represent receptors for a variety of signals (see list below). Asterisks (*) indicate mutations that have resulted in human obesity.

Receptors: GhR, ghrelin receptor; LepR, leptin receptor; InsR, insulin receptor; Mc3R, melanocortin 3 receptor; Mc4R, melanocortin 4 receptor; Y1R, Y1 subtype of neuropeptide Y (NPY) receptor. Other abbreviations: CCK, cholecystokinin; CRH, corticotrophin-releasing hormone; GLP-1, glucagon-like peptide; LHA, lateral hypothalamic area; α -MSH, α -melanocyte-stimulating hormone; NPY/AgRP, neuropeptide Y/agouti-related protein; POMC/CART, pro-opiomelanocortin/cocaine-and-amphetamine-regulated transcript; PVN, paraventricular nucleus; PYY, peptide YY; TRH, thyrotrophin-releasing hormone.

- **The central appetite-stimulating (orexigenic) pathway** in the ventromedial part of the arcuate nucleus, which expresses NPY (neuropeptide Y) and AgRP (agouti-pathway) related protein). Animal studies suggest that this pathway also decreases energy expenditure.
- **The central appetite-suppressing (anorexigenic pathway or leptin-melanocortin pathway)** in the dorsolateral part of the arcuate nucleus, which expresses POMC/CART (pro-opiomelanocortin/cocaine-and-amphetamine-regulated transcript). In this pathway, α -MSH (α -melanocyte-stimulating hormone), formed by cleavage of POMC by PC1 (prohormone convertase), exerts its appetite-suppressing effect via the Mc4R (melanocortin-4 receptors) in areas of the brain that regulate food intake and autonomic activity. Animal studies suggest that this pathway also increases energy expenditure.

These pathways interact with each other and feed into the lateral hypothalamus, which communicates with other parts of the brain, and influence the autonomic nervous system and ingestive behaviour. These central pathways are in turn influenced by a variety of peripheral signals which can also be classified as appetite stimulating or appetite suppressing.

- **Peripheral appetite-suppressing signals:** *Leptin and insulin* act centrally to activate the appetite-suppressing pathway (while also inhibiting the appetite-stimulating pathway). Since these hormones circulate in proportion to adipose tissue mass, they can be regarded as long-term signals, although they probably also modulate short-term signals (insulin also responds acutely to meal ingestion). Peptide YY (PYY) is produced by the L cells of the large bowel and distal small bowel in proportion to the energy ingested. The release of this rapidly responsive (short-acting) signal begins shortly after food intake, suggesting that the initial response involves neural pathways, before ingested nutrients reach the site of PYY production. PYY is thought to reduce appetite, at least partly through inhibition of the appetite-stimulating pathway (NPY/AgRP-expressing neurones). There are a large number of other peripheral appetite suppressing signals, including glucagon-like peptide 1 (GLP-1) and oxyntomodulin, which, like PYY, are produced by the gut in a nutrient dependent manner.
- **Peripheral appetite-stimulating signals:** *Ghrelin* is a 28-amino-acetylated peptide produced by the oxyntic cells of the fundus of the stomach. It is the first known gastrointestinal tract peptide that stimulates appetite by activating the central appetite-stimulating pathway. The circulatory concentration is high before a meal and is reduced rapidly by ingestion of a meal or glucose (*cf.* peptide YY, which increases after a meal). It may also act as a long-term signal, as its circulating concentration in weight-stable individuals is inversely related to BMI over a wide range (*cf.* insulin and leptin which are positively related to BMI, see below). It is also increased in several situations in which there is a negative energy balance, e.g. long-term exercise, very low-calorie diets, anorexia nervosa and both cancer and cardiac cachexia (an exception is vertical banded gastric bypass surgery, where its concentration is low rather than high). Recent studies suggest that another peptide, obestatin, produced by the same gene that encodes ghrelin, counteracts the increase in food intake induced by ghrelin.

The single gene mutations affecting this pathway in humans, e.g. leptin, leptin receptor, *POMC*, *Mc4R*, *PC1* and *SIM1*, are rare and recessive, with the exception of the *Mc4R*, which is common and dominant with incomplete penetrance. It appears that the *Mc4R* mutation accounts for 2–6% of human obesity. Affected individuals are obese without disturbances in pituitary function or resting energy expenditure, although children tend to be tall. However, these mutations are of little significance as obesity is predominantly polygenic in origin (the human obesity gene map has already identified several hundreds of candidate genes).

- Another system, the **endocannabinoid system**, is involved in both central and peripheral regulation of food intake and control of energy balance. There are two receptors: endocannabinoid in the brain and CB₂ in the periphery. CB₁ receptors are located in the cerebral cortex, cerebellum and hippocampus.

The control of appetite is extremely complex. For example, if one considers only one signal, i.e. leptin, there can be leptin resistance where obese individuals have high circulating leptin but with no reduction of appetite. In contrast, in acute starvation, leptin concentrations decrease to lower levels than expected from the prevailing adipose tissue mass. It is known that cytokines, such as TNF and IL-2, which are elevated in a wide range of inflammatory and traumatic conditions, also suppress appetite, although the exact pathways involved are not entirely clear. Finally, there is a range of transmitters in the central nervous system that appear to affect appetite:

- Appetite inhibitors: dopamine, serotonin, γ -aminobutyric acid
- Appetite stimulators, e.g. opioids.

Energy expenditure

Basal metabolic rate (BMR). BMR in obese subjects is higher than in lean subjects, which is not surprising since obesity is associated with an increase in lean body mass.

Physical activity. Obese patients tend to expend more energy during physical activity as they have a larger mass to move. On the other hand, many obese patients decrease their amount of physical activity. The energy expended on walking at 3 miles/hour is only 15.5 kJ/min (3.7 kcal/min) and therefore, a mild to moderate increase in physical activity plays only a small part in losing weight. Nevertheless, because increased body fat develops insidiously over many years, any change in energy balance is helpful.

Thermogenesis

About 10% of ingested energy is dissipated as heat and is unconnected with physical activity. This dietary induced thermogenesis has been reported to be lower in obese and post-obese subjects than in lean subjects. This would tend to favour energy deposition in obesity and those predisposed to obesity. However, other reports have identified no difference in dietary induced thermogenesis between lean and obese subjects.

Brown adipose tissue in animals, when stimulated by cold or food, dissipates the energy derived from ingested food into heat. This can be a major component of overall energy balance in small mammals but the effect is likely to be very small, and of doubtful clinical significance in adult humans, even though brown adipose tissue is found in humans. β_3 -adrenergic receptors are the principal receptors mediating catecholamine-stimulated lipolysis in brown adipose tissue and to a lesser extent at other sites. Drugs with β_3 -adrenergic

activities have been developed, but side-effects have limited their use.

Morbidity and mortality

Obese patients are at risk of early death, mainly from diabetes, coronary heart disease and cerebrovascular disease. The greater the obesity, the higher the morbidity and mortality rates. For example, men who are 10% overweight have a 13% increased risk of death, while the increase in mortality for those 20% overweight is 25%. The rise is less in women, and in men over 65, obesity is not an independent risk factor. Weight reduction reduces this mortality and therefore should be strongly encouraged. The benefits are probably greater in more obese subjects (Table 5.15).

Clinical features

Most patients recognize their own problems, although often they are unaware of the main foods that cause obesity. Many symptoms are related to psychological problems or social pressures, such as the woman who cannot find fashionable clothes to wear.

The degree of obesity can be assessed by comparison with tables of ideal weight for height, from the BMI (Box 5.6), and by measuring skinfold thickness. The latter should be measured over the middle of the triceps muscle; normal values are 20 mm in a man and 30 mm in a woman. A central distribution of body fat (a waist/hip circumference ratio of >1.0 in men and >0.9 in women) is associated with a higher risk of morbidity and mortality than is a more peripheral distribution of body fat (waist/hip ratio <0.85 in men and <0.75 in women). This is because fat located centrally, especially inside the abdomen, is more sensitive to lipolytic stimuli, with the result that the abnormalities in circulating lipids are more severe.

Table 5.15 Potential benefits that may result from the loss of 10 kg in patients who are initially 100 kg and suffer from co-morbidities

Mortality	20–25% fall in total mortality 30–40% fall in diabetes-related deaths 40–50% fall in obesity-related cancer deaths
Blood pressure	Fall of about 10 mmHg (systolic and diastolic)
Diabetes	Reduces risk of developing diabetes by >50% 30–50% fall in fasting blood glucose 15% fall in HbA _{1c}
Serum lipids	10% fall in total cholesterol 15% fall in LDL cholesterol 30% fall in triglycerides 8% increase in HDL cholesterol

Box 5.6 Ranges of body mass index (BMI) used to classify degrees of overweight and associated risk of co-morbidities

WHO classification	BMI (kg/m ²)	Risk of co-morbidities
Overweight	25–30	Mildly increased
Obese	>30	
Class I	30–35	Moderate
Class II	35–40	Severe
Class III	>40	Very severe

Table 5.16 shows the conditions and complications that are associated with obesity. The relationship between cardiovascular disease (hypertension or ischaemic heart disease), hyperlipidaemia, smoking, physical exercise and obesity is complex. Difficulties arise in interpreting mortality figures because of the number of factors involved. Many studies do not differentiate between the types of physical exercise taken or take into account the cuff-size artefact in the measurement of blood pressure (an artefact will occur if a large cuff is not used in patients with a large arm). Nevertheless, obesity almost certainly plays a part in all of these diseases and should be treated. An exception is that stopping smoking, even if accompanied by weight gain, is more beneficial than any of the other factors. Physical fitness is also helpful, and there is some evidence to suggest that a fit obese person may have similar or even lower cardiovascular risk than a leaner unfit person.

Metabolic syndrome

There are two classification systems which are shown in Table 5.17. The differences are:

- A large waist is an absolute requirement for the International Diabetes Federation (IDF), but not in the ATP III NCEP.

Table 5.16 Conditions and complications associated with obesity

Psychological Osteoarthritis of knees and hips Varicose veins Hiatus hernia Gallstones Postoperative problems Back strain Accident proneness Obstructive sleep apnoea Hypertension	Breathlessness Ischaemic heart disease Stroke Diabetes mellitus (type 2) Hyperlipidaemia Menstrual abnormalities Increased morbidity and mortality Increased cancer risk Heart failure
---	--

Table 5.17 Classification systems for metabolic syndrome: ATP III of the National Cholesterol Education Programme (NCEP) and International Diabetes Federation (IDF)

Risk factor	ATP III NCEP (any 3 of the 5 features)	International Diabetes Federation (large waist + any other 2 features)
Waist circumference		
Men	>102 cm (40 in)	>94 cm (37 in)
Women	>88 cm (35 in)	>80 cm (35 in)
Triglycerides	>1.7 mmol/L (150 mg/dL)	1.7 mmol/L (150 mg/dL)
HDL cholesterol		
Men	<1.03 mmol/L (40 mg/dL)	<1.03 mmol/L (40 mg/dL)
Women	<1.29 mmol/L (50 mg/dL)	<1.29 mmol/L (50 mg/dL)
Blood pressure	>130/85 mmHg	>130/85 mmHg
Fasting glucose	>5.6 mmol/L (100 mg/dL)	>5.6 mmol/L (100 mg/dL)
ATP III, Adult Treatment Panel 3.		

- The IDF criteria use lower cut-off values for waist circumference (close to values of people with a BMI of 25 kg/m²) and lower fasting blood glucose concentrations.

This means that the prevalence of metabolic syndrome will be higher using the IDF criteria and the IDF criteria will identify at-risk patients at an earlier stage. This could lead to further investigations following on from the initial screening, and earlier institution of preventative as well as therapeutic measures. Other classification systems also exist, e.g. using BMI (an overall measure of obesity) instead of waist circumference (a measure of central obesity, which is more likely to be associated insulin resistance).

Overweight/central obesity and insulin resistance, which causes glucose and lipid disturbances, seem to form the basis of many features of the metabolic syndrome. Early treatment of obesity and the metabolic syndrome can avoid development of clinical diabetes and its complications.

The metabolic syndrome is a combination of risk factors (Table 5.17). Its overall role in the prediction of the risk of cardiovascular disease has been questioned as the sum of the combined risk factors in the syndrome does not offer more than the individual factors added together.

Treatment

Dietary control

This largely depends on a reduction in calorie intake. The most common diets allow a daily intake of approximately 4200 kJ (1000 kcal), although this may need to be nearer 6300 kJ (1500 kcal) for someone engaged in physical work. Very low calorie diets are also advocated by some, usually over shorter periods of time, but unless they are accompanied by changes in lifestyle, weight regain is likely. Patients must realize that prolonged dieting is necessary for large amounts of fat to be lost. Furthermore, a permanent change in eating habits is required to maintain the new low weight. It is relatively easy for most people to lose the first few kilograms, but long-term success in moderate obesity is poor (no more than 10%). Most obese people oscillate in weight; they often regain the lost weight, but many manage to lose weight again. This 'cycling' in bodyweight may play a role in the development of coronary artery disease.

Many dietary regimens aim to produce a weight loss of approximately 1 kg/week. Weight loss will be greater initially owing to accompanying protein and glycogen breakdown and consequent water loss. After 3–4 weeks, further weight loss may be very small because only adipose tissue is broken down and there is less accompanying water loss.

Patients must understand the principles of energy intake and expenditure, and the best results are obtained in educated, well-motivated patients. Constant supervision by healthcare professionals, by close relatives or through membership of a slimming club helps to encourage compliance. It is essential to establish realistic aims. A 10% weight loss, which is regarded by some as a 'success' (see Table 5.15), is a realistic initial aim.

An increase in exercise will increase energy expenditure and should be encouraged – provided there is no contraindication – since weight control is usually not achieved without exercise. The effects of exercise are complex and not entirely understood. However, exercise alone will usually produce little long-term benefit. On the other hand there is evidence to suggest that in combination with dietary therapy, it can prevent weight being regained. In addition, regular exercise (30 min daily) will improve general health.

Box 5.7 Constituents of a diet for weight loss

- 4200 kJ (1000 kcal) per day made up of >50 g protein, approximately 100 g of carbohydrate and 40 g of fat
- Carbohydrate should be in the form of complex carbohydrates such as vegetables and fruit rather than simple sugars
- Alcohol should be discouraged (contains 29 kJ/g (7 kcal/g)); it can be substituted for other foods in the diet, but it often reduces the willpower
- With a varied diet, vitamin and mineral intake will be adequate and supplements are not necessary.

The diet should contain adequate amounts of protein, vitamins and trace elements (Box 5.7).

A balanced diet, attractively presented, is of much greater value and safer than any of the slimming regimens often advertised in magazines.

A wide range of diets are available, including low-fat or low-carbohydrate diets, and some suit certain individuals better than others. The following general statements can be made about them:

- All low-calorie diets produce loss of bodyweight and fat, irrespective of dietary composition. Short-term weight loss is faster on low-carbohydrate diets, as a result of greater loss of body water, which is regained after the end of dietary therapy.
- Very low-fat diets are often low in vitamins E, B₁₂, and zinc. Very low-carbohydrate diets may be nutritionally inadequate, and may lead to deficiencies.
- Low-fat diets decrease LDL triglycerides and increase HDL, whereas low-carbohydrate diets produce a greater decrease in HDL and triglyceride, with no change in LDL.
- There are some potential long-term concerns with low-carbohydrate diets (high in fat and protein), including increased risk of osteoporosis, renal stones and atheroma (due to high saturated fat, high *trans* fat and cholesterol and the lack of fruits, vegetables and whole grains) but long-term studies are lacking.
- Low-energy-density diets, often bulky and rich in fibre and complex carbohydrates, may be more satiating but they are often less palatable than high-energy-dense diets, which may affect long-term compliance.
- Liquids, e.g. soft drinks, appear to be less satiating than solid foods.
- A recent study has shown that Mediterranean and low-carbohydrate diets are as effective as a low-fat diet for weight loss.

Behavioural modification

The aim of behavioural modification is to encourage the patient to take personal responsibility for changing lifestyle, which will determine dietary habits and physical activity. Family therapy may also be useful, especially when it involves obese children. It can be time-consuming and expensive. Cognitive behavioural therapy is even more time-consuming and expensive.

Drug therapy

Drugs can be used in the short term (up to 3 months) as an adjunct to the dietary regimen, but they do not substitute for strict dieting.

Dietz WH. Reversing the tide of obesity. *Lancet* 2011; 378:744–746; plus Series on obesity: 804–814; 815–825; 826–837; 838–847.

Centrally acting drugs:

- Drugs acting on both serotonergic and noradrenergic pathways, e.g. sibutramine (now withdrawn in Europe due to side-effects). Other drugs, such as lorcaserin, a selective 5-HT_{2C} receptor agonist, are being evaluated.
- Cannabinoid-1 receptor blockers, e.g. rimonabant (now withdrawn due to depression/suicide risk), acting on the endocannabinoid system.
- Drugs acting on the noradrenergic pathways do suppress appetite but all have been withdrawn, at least in the UK, because of cardiovascular side-effects.

Peripherally acting drugs:

- **Orlistat** is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption and aids weight loss. Weight regain occurs after the drug is stopped. It has been used continuously in a large-scale trial for up to 2 years. The patients complain of diarrhoea during treatment and to avoid this, take a low-fat diet resulting in weight loss.
- **Glucagon-like peptide 1 (GLP-1)** suppresses appetite and injections have been used to treat obesity (Fig. 5.9) and type 2 diabetes mellitus (p. 1011).

A systematic review of long-term pharmacotherapy concluded that there was a paucity of long-term studies with anti-obesity agents, and that in weight loss trials of 1-year duration, appear to be only modestly effective in promoting weight loss (about 3–4 kg greater weight loss, respectively than the control group). Other randomized trials show that a combination of lifestyle modification and pharmacotherapy produce greater weight loss than either treatment alone, but the withdrawal of several anti-obesity drugs suggests that a pharmacotherapeutic magic bullet to treat obesity without substantial short-term and long-term effects is not yet available although the search continues. Alternative forms of treatment should be considered (unless obesity and its risks are accepted as part of modern society).

Surgical treatment

Surgery is used in some cases of morbid obesity (BMI >35 kg/m²) or patients with a BMI >30 kg/m² and obesity related complications, after conventional medical treatments have failed. It can be used as a first-line option for individuals with a BMI >50 kg/m². Fitness for surgery should be checked, especially in older people. A variety of gastrointestinal surgical procedures have been used. They fall into three main groups (Fig. 5.10):

Restrictive procedures, which restrict the ability to eat (e.g. adjustable gastric banding, vertical banded gastroplasty and sleeve gastroplasty).

Malabsorptive procedures, which reduce the ability to absorb nutrients (e.g. biliopancreatic diversion and Roux-en-Y gastric bypass). The malabsorptive procedures cause nutrient deficiencies, malnutrition and in some cases, anastomotic leaks and the dumping syndrome (e.g. with the duodenal switch).

Restrictive plus malabsorptive procedures (e.g. duodenal switch, Roux-en-Y gastric bypass, intragastric balloon).

The procedures all have advantages and disadvantages, and there is controversy about the procedure of choice for specific groups of patients. The restrictive procedures are more straightforward than the complex bypass procedures. The adjustable gastric banding procedure, although attractive in concept, especially since it can be undertaken laparoscopically with a lower perioperative mortality (<0.3%) than the other procedures (~1%), can be associated with erosion and slippage of the band, as well problems with the port, making repeat operations a frequent requirement (>10% of cases). The sleeve gastrectomy is associated with heartburn and greater risk of weight regain, but a biliary pancreatic diversion (duodenal switch) can be added at a later time.

There is a need to carefully monitor nutrient status with blood tests and provide supplements of vitamins and minerals (including iron and calcium). Weight loss following the combined restrictive and malabsorptive procedures tends to be greater than with either procedure alone.

A systematic analysis of several bariatric surgical procedures concluded that, in comparison to non-surgical treatments, they produced significantly more weight loss (23–37 kg), which was maintained to 8 years and associated with improvement in quality of life and co-morbidities.

Liposuction, the removal of large amounts of fat by suction (liposuction), does not deal with the underlying problem and weight regain frequently occurs. There appears to be no reduction in cardiovascular risk factors with the procedure.

Prevention

Preventing obesity must always be the goal because most obese people find it difficult to maintain any weight loss they have managed to achieve. All health professionals must be aware of the dangers of obesity and encourage children, young as well as older adults, from gaining too much weight.

Figure 5.10 Examples of surgery procedures to treat morbid obesity. (a) Restrictive procedure: gastric banding with subcutaneous port attached to anterior abdominal wall so that fluid can be injected into the adjustable band around the upper stomach. (b) Restrictive plus malabsorptive procedures: Roux-en-Y gastric bypass, in which food bypasses through a small stomach pouch and bypasses the proximal small bowel. (Courtesy of Mr Amit Patel.)

A small gain each year over a long period produces an obese individual for whom treatment is difficult. Public health policies should consider creation of public places to encourage physical activity and fitness, education about the benefits of losing weight or not gaining it, through healthy eating and physical activity, and changes in food composition (alternatives to high-fat, high-energy-dense foods).

Since the present obesity epidemic has resulted from lifestyle changes, it is appropriate to promote lifestyle changes, not only as the first-line therapy for most overweight and obese individuals, but also in the prevention of overweight and obesity. Lifestyle modification would involve changes in the amount of time watching television and using computers, use of bicycle paths, dietary changes and educational activities of patients and public, parents and children. To prevent long-term weight gain after any of the therapies discussed above, each therapy should be part of a package that involves lifestyle modification.

NUTRITIONAL SUPPORT IN THE HOSPITAL PATIENT

Nutritional support is recognized as being necessary in many hospitalized patients. The pathophysiology and hallmarks of malnutrition have been described earlier (p. 200); here the forms of nutritional support that are available are discussed, along with special nutritional requirements in some diseases.

Principles

Some form of nutritional supplementation is required in those patients who cannot eat, should not eat, will not eat or cannot eat enough. All patients should be screened for malnutrition on admission and the findings linked to a care plan, preferably under the supervision of a trained multidisciplinary team. The Council of Europe has produced 10 key characteristics of good nutritional care in hospital (see: bapen.org.uk). Plans are discussed with patients and consent is taken for any invasive procedure (e.g. nasogastric tube, parenteral nutrition). If the patient is unable to give consent, the healthcare team should act in the patient's best interest, taking into account previously expressed wishes of the patient and views of the family. It is usually necessary to provide nutritional support for:

- all severely malnourished patients on admission to hospital
- moderately malnourished patients who, because of their physical illness, are not expected to eat for more than 3–5 days
- normally nourished patients expected not to eat for more than 5 days or to eat less than half their intake for more than 8–10 days.

Enteral rather than parenteral nutrition should be used if the gastrointestinal tract is functioning normally.

In *re-feeding syndrome*, the shifts of water and electrolytes that occur after parenteral and enteral nutrition can be life-threatening. Carbohydrate intake stimulates insulin release which leads to cellular uptake of phosphate, potassium and magnesium. Complications include hypophosphataemia, hypokalaemia, hypomagnesaemia and fluid overload because of sodium retention (decreased renal excretion of sodium and water). Patients who have eaten little or nothing for more than 5 days should initially receive no more than 50% of their energy requirements (NICE guidelines).

Nutritional requirements for adults

- **Water.** Typical requirements are ~2–3 L/day. Increased requirements occur in patients with large-output fistulae, nasogastric aspirates and diarrhoea. Reduced requirements occur in patients with oedema, hepatic failure, renal failure (oliguric and not dialysed) and brain oedema.
- **Energy.** Typical requirements are ~7.5–10.0 MJ/day (1800–2400 kcal/day). Disease increases resting energy expenditure but decreases physical activity. Extra energy is given for repletion and reduced energy for obesity.
- **Protein.** Typically 10–15 g N/day (62–95 g protein/day) or 0.15–0.25 g N/kg per day (0.94–1.56 g protein/kg per day). Extra protein may be needed in severely catabolic conditions, such as extensive burns.
- **Major minerals.** Typical requirements for sodium and potassium are 60–100 mmol/day. Increased requirements occur in patients with gastrointestinal effluents. The excretion of these minerals in various effluents can provide an indication of the additional requirements (see Table 13.10). Low requirements may be necessary in those with fluid overload (or patients with hyponatraemia and hyperkalaemia). The requirements of calcium and magnesium are higher for enteral than for parenteral nutrition because only a proportion of these minerals is absorbed by the gut.
- **Trace elements.** For trace elements such as iodide, fluoride and selenium that are well absorbed, the requirements for enteral and parenteral nutrition are similar. For other trace elements, such as iron, zinc, manganese and chromium, the requirements for parenteral nutrition are substantially lower than for enteral nutrition (Fig. 5.11).
- **Vitamins.** Many vitamins are given in greater quantities in patients receiving parenteral nutrition than in those receiving enteral nutrition (Fig. 5.12). This is because patients on parenteral nutrition may have increased requirements, partly because of severe disease, partly

Figure 5.11 Trace elements. because they may already have depleted pools of vitamins, and partly because some vitamins degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.

Enteral nutrition (EN)

Feeds can be given by various routes:

- By mouth (food can be supplemented with solid or liquid supplements with multiple benefits).
- By fine-bore nasogastric tube (see [Practical Box 5.1](#))
- Percutaneous endoscopic gastrostomy (PEG) is useful for patients who need enteral nutrition for a prolonged period (e.g. >30 days), such as those with swallowing problems following a head injury or in elderly people after a stroke. A catheter is placed percutaneously into the stomach under endoscopic control ([Fig. 5.13](#)).
- With needle catheter jejunostomy, a fine catheter is inserted into the jejunum at laparotomy and brought out through the abdominal wall.

Diet formulation ([Table 5.18](#))

A polymeric diet with whole protein and fat can be used, except in patients with severely impaired gastrointestinal function who may require a predigested (i.e. elemental) diet. In these patients, the nitrogen source is purified low-molecular-weight peptides or amino acid mixtures, with sometimes the fat being given partly as medium-chain triglycerides.

Management

Daily amounts of diet vary between 1.5 and 2.5 L, but small amounts are started in patients with suspected poor gastric emptying and severe malnutrition (to avoid the re-feeding syndrome).

Table 5.18 Standard enteric diet, providing 8.4 MJ/day (= 2000 kcal)

Energy

Carbohydrate as glucose polymers (49–53% of total energy). Fat as triglycerides (30–35% of total energy)

Nitrogen

Whole protein (10–14 g of nitrogen/day). Additional electrolytes, vitamins and trace elements

Features

Ratio of energy to nitrogen kJ:g = 620:1 (kcal:g = 150:1). Osmolality = 285–300 mOsm/kg

Practical Box 5.1

Enteral feeding via nasogastric tube

The procedure should be explained to the patient and consent taken.

Procedure

- Insert fine-bore tube intranasally with wire stylet.
- Confirm position of tube in stomach by aspiration of gastric contents (check pH) and auscultation of the epigastrium.
- Check by X-ray if aspiration or auscultation is unsuccessful.

Problems

- No satisfactory way of keeping nasogastric tubes in place (up to 60% come out).

Main complications

- Regurgitation and aspiration into bronchus.
- Blockage of the nasogastric tube.
- Gastrointestinal side-effects, the most common being diarrhoea.
- Metabolic complications including hyperglycaemia and hypokalaemia, as well as low levels of magnesium, calcium and phosphate.

Hypercatabolic patients require a high supply of nitrogen (15 g daily) and often will not achieve positive nitrogen balance until the primary injury is resolved.

The success of enteral feeding depends on careful supervision of the patient, with monitoring of weight, biochemistry and diet charts.

Parenteral nutrition

Peripheral parenteral nutrition

Specially formulated mixtures for peripheral use are available, with a low osmolality (<800 mosmol/L) and containing lipid emulsions. Heparin and corticosteroids can be added to the infusion and local application of glyceryl trinitrate patches reduces the occurrence of thrombophlebitis and prolongs catheter life.

- A peripheral cannula can be inserted into a mid-arm vein (20 cm) and can be left for up to 5 days.
- A longer (60 cm) peripherally inserted central catheter (PICC) inserted into an antecubital fossa vein has its distal end lying in a central vein; here there is less risk of thrombophlebitis and hyperosmolar solutions can be given. With careful management, PICCs can be used for up to about a month.

Peripheral parenteral nutrition is often preferred initially, allowing time to consider the necessity for having to insert a central venous catheter.

Parenteral nutrition via a central venous catheter (PN) (see Practical Box 5.2)

A silicone catheter is placed into a central vein, usually using the infraclavicular approach to the subclavian vein. The skin-entry site should be dressed carefully and not disturbed unless there is a suggestion of catheter-related sepsis.

Complications of catheter placement include central vein thrombosis, pneumothorax and embolism, but one of the commonest problems is catheter-related sepsis. Organisms, mainly staphylococci, enter along the side of the catheter, leading to septicaemia. Sepsis can be prevented by careful and sterile placement of the catheter, by not removing the dressing over the catheter entry site, and by not giving other substances (e.g. blood products, antibiotics) via the central vein catheter.

Sepsis should be suspected if the patient develops fever and leucocytosis. In two-thirds of cases, organisms can

be grown from the catheter tip after removal. Treatment involves removal of the catheter and appropriate systemic antibiotics.

Nutrients

With PN, it is possible to provide sufficient nitrogen for protein synthesis and calories to meet energy requirements. Electrolytes, vitamins and trace elements are also necessary. All of these substances are infused simultaneously.

Nitrogen source

Most patients receive at least 11–15 g N/day, in the form of synthetic L-amino acids.

Energy source

This is provided by glucose, with additional calories provided by a fat emulsion. Fat infusions provide a greater number of calories in a smaller volume than can be provided by carbohydrate. Fat infusions are not hypertonic and they also prevent essential fatty acid deficiency.

Essential fatty acid deficiency has been reported in long-term parenteral nutritional regimens without fat emulsions. It causes a scaly skin, hair loss and a delay in healing.

Electrolytes, vitamins and trace elements

Initially, the electrolyte status should be monitored on a daily basis and electrolyte solutions given as appropriate. Fat- and water-soluble vitamins and minerals including trace elements should be given routinely (see Figs 5.12, 5.13).

Administration and monitoring

Peripheral parenteral nutrition. Administered via 3-L bags over 24 hours, with the constituents being premixed under sterile conditions by the pharmacy. Table 5.19 shows the composition which provides 9 g of nitrogen and 1700 calories in 24 h.

Central venous PN regimen. Most hospitals now use premixed 3-L bags. A standard parenteral nutrition regimen which provides 14 g of nitrogen and 2250 calories over 24 hours is also given in Table 5.19. Monitoring includes:

Practical Box 5.2

Central catheter placement for parenteral nutrition

This should be performed only by experienced clinicians under aseptic conditions in an operating theatre.

Give an explanation and obtain consent from the patient.

- The patient is placed supine with 5° of head-down tilt to avoid air embolism.
- The skin below the midpoint of the right clavicle is infiltrated with 1–2% lidocaine and a 1 cm skin incision is made.
- A 20-gauge needle on a syringe is inserted beneath the clavicle and first rib and angled towards the tip of a finger held in the suprasternal notch.
- When blood is aspirated freely, the needle is used as a guide to insert the cannula through the skin incision and into the subclavian vein.
- The catheter is advanced so that its tip lies in the distal part of the superior vena cava.
- A skin tunnel is created under local anaesthetic using an introducer inserted through a point about 10 cm below and medial to the incision and passed upwards to the incision.
- The proximal end of the catheter (with hub removed) is passed backwards through the introducer to emerge 10 cm below the clavicle, where it is sutured to the chest wall.
- The original infraclavicular entry incision is now sutured.

Table 5.19 Examples of parenteral nutrition regimens

Peripheral: all mixed in 3-L bags and infused over 24 hours		
Nitrogen	L-amino acids	1 L
	9 g/L	
Energy	Glucose 20%	1 L
	Lipid 20%	0.5 L
	+ Trace elements, electrolytes, and water-soluble and fat-soluble vitamins, heparin 1000 UL and hydrocortisone 100 mg; insulin is added if required. Nitrogen 9 g, non-protein calories 7206 kJ (1700 kcal)	
<hr/>		
Central: all mixed in 3-L bags and infused over 24 hours		
Nitrogen	L-amino acids	1 L
	14 g/L	
Energy	Glucose 50%	0.5 L
	Glucose 20%	0.5 L
	+ Lipid 10% as either Intralipid or Lipofundin	0.5 L
	Fractionated soya oil 100 g/L, Soya oil 50 g, medium-chain triglycerides 50 g/L	
	+ Electrolytes, water-soluble vitamins, fat-soluble vitamins, trace elements, heparin and insulin may be added if required. Nitrogen 14 g, non-protein calories 9305 kJ (2250 kcal)

Zaloga GP. Parenteral nutrition in adult inpatients with functioning gastrointestinal tracts: assessment of outcomes. *Lancet* 2006; 367: 1101–1111.

- **Blood tests.** Daily plasma electrolytes and glucose (at least initially). Twice weekly FBC, liver biochemistry and function, calcium, phosphate, and magnesium, zinc and triglycerides weekly.
- **Nutritional status.** Weekly weight and skinfold thickness if appropriate callipers are available. Daily weight changes reflect changes in fluid balance.
- **Nitrogen balance** (p. 197) assessment, but this requires complete collections of urine.

Complications

- Mechanical: insertional trauma and catheter-related (see above)
- Metabolic, e.g. hyperglycaemia (insulin therapy is usually necessary), fluid and electrolyte disturbances, hypercalcaemia, nutrient deficiencies (if inadequately provided)
- Organ or tissue dysfunction, e.g. abnormal liver dysfunction, respiratory distress and metabolic bone disease
- Others, e.g. rare allergic reactions to lipid, and psychological disturbances.

The need for major improvements in the practice of parenteral nutrition in British hospitals has been emphasized by the National Confidential Enquiry into Patient Outcome and Death (NCEPOD). This included need for improvements at every level: assessment, monitoring and follow-up, including appropriate care of lines to avoid catheter-related sepsis and documentation.

NUTRITIONAL SUPPORT IN THE HOME PATIENT

In both high- and low-income countries, there is considerably more undernutrition in the community than in hospital. However, the principles of care are very similar: detection of malnutrition and the underlying risk factors; treatment of underlying disease processes and disabilities; correction of specific nutrient deficiencies and provision of appropriate nutritional support. This typically begins with dietary advice, and may involve the provision of 'meals on wheels' by social services. A systematic review of the use of nutritional supplements in the community came to the following conclusions:

- Supplements are generally of more value in *patients with a BMI <20 kg/m² and children with growth failure* (weight for height <85% of ideal) than in those with better anthropometric indices. They are likely to be of little or no value in patients with little weight loss and a BMI >20 kg/m². The supplemental energy intake in such subjects largely replaces oral food intake.
- Supplements may be of value in *weight-losing patients* (e.g. >10% weight loss compared to pre-illness) with a BMI >20 kg/m², and in *children with deteriorating growth performance* without chronic protein-energy undernutrition.
- The functional benefits vary according to the patient group. In patients with *chronic obstructive airways disease* the observed functional benefits were increased respiratory muscle strength, increase in handgrip strength, and an increase in walking distance/duration of exercise. In the *elderly* the benefits were reduced number of falls, or increase in activities of daily living, and reduced pressure sore surface area. In patients with

HIV/AIDS there were changes in immunological function and improved cognition. Patients with *liver disease* experienced a lower incidence of severe infections and had a lower frequency of hospitalization.

- **Acceptability and compliance** are likely to be better when a choice of supplements (of type, flavour, consistency) and schedule is decided in conjunction with the patient and/or carer. Changes in these may be necessary when there is a change in patterns of daily activities, disease status, and 'taste fatigue' with prolonged use of the same supplement.
- **Nutritional counselling and monitoring** are recommended before and after the start of supplements (see below).

Some patients receive enteral tube feeding or parenteral nutrition at home. At any one point in time in developed countries enteral tube feeding occurs more frequently at home than in hospital.

Home enteral nutrition

In adults, the commonest reason for starting home tube feeding is for swallowing difficulties. This involves patients with neurological disorders, such as motor neurone disease, multiple sclerosis and Parkinson's disease, but the commonest single diagnosis is cerebrovascular disease. Approximately 2% of patients who have had a stroke in the UK receive home enteral tube feeding (HETF). However, in a British Nutrition survey of patients with these disorders (apart from Parkinson's), only 15% in total were able to return to oral feeding after 1 year.

The swallowing capabilities of patients should be assessed regularly in order to avoid unnecessary tube feeding. The patients and/or carers should have adequate training, contacts with appropriate health professions, and a reliable delivery service for feeds and ancillary equipment. They should also be clear about how to manage simple problems associated with the feeding tube, which is usually a gastrostomy tube rather than a nasogastric tube.

Home parenteral nutrition

Home parenteral nutrition is practised much less frequently, usually under the supervision of specialist centres. The potential value of intestinal transplantation in patients with long-term intestinal failure is still being assessed.

FOOD ALLERGY AND FOOD INTOLERANCE

Many people ascribe their various symptoms to food, and many such sufferers are seen and started on exclusion diets. The scientific evidence that food does harm is in most instances weak, although adverse reactions to food certainly exist. These can be divided into those that involve immune mechanisms (*food allergy*) and those that do not (*food intolerance*).

Food allergy

Food allergy, which is estimated to affect up to about 5% of young children and about 1–2% of adults, may be IgE mediated or non-IgE mediated (T-cell mediated). The IgE-mediated reactions tend to occur early after a food challenge (within minutes to an hour). Adults tend to be allergic to fish, shellfish and peanuts, while children tend to be allergic to cow's milk, egg white, wheat and soy. Peanuts are very allergenic and peanut allergy persists throughout life. The following conditions can result from food allergy:

- **Acute hypersensitivity.** An example is urticaria, vomiting or diarrhoea after eating nuts, strawberries or shellfish. These IgE-mediated reactions do not usually produce clinical problems as the patients have already learned to avoid the suspected food. Inadvertent ingestion of the incriminating food can sometimes occur, leading to angioneurotic oedema (p. 1211).
- **Eczema and asthma.** These tend to affect young children and are often due to egg and are IgE mediated.
- **Rhinitis and asthma.** These have been produced by foods such as milk and chocolate, mainly in atopic subjects.
- **Chronic urticaria.** This has been treated successfully by an exclusion diet.
- **Food-sensitive enteropathy.** This may manifest itself as coeliac disease (gluten (wheat) sensitive enteropathy) and cow's milk enteropathy (in infants), and is T-cell mediated.

Food intolerance

- **Migraine.** This sometimes follows the intake of foods such as chocolate, cheese and alcohol, which are rich in certain amines, such as tyramine. Patients on monoamine oxidase inhibitors, which are involved in the metabolism of these amines, are particularly vulnerable.
- **Irritable bowel syndrome.** In some patients, this seems to be related to ingestion of certain food items, such as wheat, but the mechanisms are not clearly defined.
- **Chinese restaurant syndrome.** Monosodium glutamate, a flavour enhancer used in cooking Chinese food, may produce dizziness, faintness, nausea, sweating and chest pains.
- **Lactose intolerance.** Patients develop abdominal bloating and diarrhoea following ingestion of lactose, which is present in milk (p. 264). This is probably the commonest form of food intolerance worldwide, and may be genetic in origin.
- **Phenylketonuria.** This can also be classified as a form of food intolerance, and is due to lack of phenylalanine hydroxylase, which is necessary for the metabolism of phenylalanine present in dietary protein.

A number of other inborn errors of metabolism can also be regarded as forms of food intolerance.

Food intolerance may be due to a constituent of food (e.g. the histamine in mackerel or canned food or the tyramine in cheeses); chemical mediators released by food (e.g. histamine may be released by tomatoes or strawberries); or toxic chemicals found in food (e.g. the food additive tartrazine). Many other additives and compounds with certain E numbers have been implicated as causing reactions, but the evidence is poor.

There is little or no evidence to suggest that diseases such as arthritis, behaviour and affective disorders and Crohn's disease are due to ingestion of a particular food. Multiple vague symptoms such as tiredness or malaise are also not due to food allergy. Most of the patients in this group are suffering from a psychiatric disorder (p. 1185).

Management

- A careful history may help to delineate the causative agent, particularly when the effects are immediate.
- Skin-prick testing with allergen and measurement in the serum of antigen or antibodies have not correlated

with symptoms and are usually misleading. 'Fringe' techniques such as hair analysis, although widely advertised, are of no value.

- Diagnostic exclusion diets are sometimes used, but they are time-consuming. They can occasionally be of value in identifying a particular food causing problems.
- Dietary challenge consists of the food and the test being given sublingually or by inhalation in an attempt to reproduce the symptoms. Again, this may be helpful in a few cases.
- Most people who have acute reactions to food realize it and stop the food, and do not require medical attention. In the remainder of patients, a small minority seem to be helped by modifying their diet, but there is no good scientific evidence to support these exclusion diets.

ALCOHOL

Although alcohol is not a nutrient, it is consumed in large quantities all over the world. In many countries, alcohol consumption is becoming a major medical and social problem (see p. 1163). It increases morbidity and mortality in a variety of ways, including effects on heart disease, stroke, cancers, liver and neurological/psychiatric problems, and it is associated with nutritional deficiencies and abnormal metabolism of drugs.

Ethanol (ethyl alcohol) is oxidized, in the steps shown in Box 5.8, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide and water.

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric mucosa may contribute substantially to ethanol metabolism.

Ethanol itself produces 29.3 kJ/g (7 kcal/g), but many alcoholic drinks also contain sugar, which increases their calorific value. For example, one pint of beer provides about 1045 kJ (250 kcal), so the heavy drinker will be unable to lose weight if he or she continues to drink.

Effects of excess alcohol consumption

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- Alcohol dependence syndrome (p. 1182)
- Physical damage to various tissues.

Each unit of alcohol (defined as one half pint of normal beer, one single measure of spirit or one small glass of wine) contains 8 g of ethanol (Fig. 5.14). All the long-term effects of excess alcohol consumption are due to excess ethanol,

Box 5.8 The main pathways of ethanol oxidation

- **Alcohol dehydrogenase:**

- **The liver microsomal enzyme oxidizing system (MEOS)** including the specific P450 enzyme, CYP2E1, which is induced by ethanol:

Figure 5.14 Measures of 1 unit of alcohol.

Box 5.9 Guide to sensible drinking of alcohol

Daily maximum

- 3 units for men 2 units for women

To help achieve this:

- Use a standard measure
- Do not drink during the daytime
- Have alcohol-free days each week

Remember

- Health can be damaged without being 'drunk'. Regular heavy intake is more harmful than occasional binges
- Do not drink to 'drown your sorrows'
- In the UK, the drink-before-driving limit of alcohol in the blood is 800 mg/L (80 mg%)
- One unit of alcohol is eliminated per hour, therefore spread drinking time
- Food decreases absorption and therefore results in a lower blood alcohol level
- 4–5 units are sufficient to put the blood alcohol level over the legal driving limit in a 70 kg man (less in a lighter person).

irrespective of the type of alcoholic beverage, i.e. beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isoamyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.

The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients, the liver is affected, in others, the brain or muscle. The differences may be genetically determined.

Thiamin deficiency contributes to both neurological (confusion, Wernicke–Korsakoff syndrome; see p. 1091) and some of the non-neurological manifestations (cardiomyopathy). Susceptibility to damage of different organs is variable and the figures given in Box 5.9 are given only as a guide to sensible drinking. Heavy persistent drinkers for many years are at greater risk than heavy sporadic drinkers.

Liver disease

In general, the effects of a given intake of alcohol seem to be worse in women. The following figures are for men and should be reduced by 50% for women:

- High risk: 160 g ethanol per day (20 single drinks)
- Medium risk: 80 g ethanol per day (10 single drinks)
- Little risk: 40 g ethanol per day (five single drinks).

Alcohol consumption in pregnancy

Women are advised not to drink alcohol at all during pregnancy because even small amounts of alcohol consumed

Table 5.20 Physical effects of excess alcohol consumption

Central nervous system

- Epilepsy (p. 1114)
- Wernicke–Korsakoff syndrome (p. 1091)
- Polyneuropathy (p. 1147)

Muscles

- Acute or chronic myopathy

Cardiovascular system

- Cardiomyopathy (p. 771)
- Beriberi heart disease (p. 209)
- Cardiac arrhythmias
- Hypertension

Metabolism

- Hyperuricaemia (gout)
- Hyperlipidaemia
- Hypoglycaemia
- Obesity

Endocrine system

- Pseudo-Cushing syndrome

Respiratory system

- Chest infections

Gastrointestinal system

- Acute gastritis (including bleeding p. 254)
- Carcinoma of the oesophagus or large bowel
- Pancreatic disease
- Liver disease (fatty liver, hepatitis, cirrhosis; p. 342)

Haemopoiesis

- Macrocytosis (due to direct toxic effect on bone marrow or folate deficiency)
- Thrombocytopenia
- Leucopenia

Bone

- Osteoporosis
- Osteomalacia

can lead to 'small babies'. The fetal alcohol syndrome is characterized by mental retardation, dysmorphic features and growth impairment; it occurs in fetuses of alcohol-dependent women.

A summary of the physical effects of alcohol is given in Table 5.20. Details of these diseases are discussed in the relevant chapters. The effects of alcohol withdrawal are discussed on page 1183.

INTRODUCTION

The gastrointestinal tract has many functions such as digestion, absorption and excretion as well as the synthesis of an array of hormones, growth factors and cytokines. In addition, a complex enteric nervous system has evolved to control its function and communicate with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest sources of foreign antigens to which the body is exposed, it houses well-developed arms of both the innate and acquired immune system.

In **developed countries** gastrointestinal symptoms are a common reason for attendance to primary care clinics and to hospital outpatients. Approximately 75% of these consultations are for non-organic symptoms. The clinician's main task is therefore to recognize when organic disease must be sought or excluded, remembering that 20% of all cancers occur in the gastrointestinal tract (Fig. 6.1). In **developing countries**, malnutrition and poor hygiene make infection a more probable diagnosis. The clinician needs to recognize and treat these infections promptly and also help with prevention by encouraging good hygiene.

GASTROINTESTINAL SYMPTOMS AND SIGNS

Stomatitis and 'burning mouth' sensation

Stomatitis is inflammation in the mouth from any cause, such as ill-fitting dentures. Angular stomatitis is inflammation of the corners of the mouth.

The 'burning mouth syndrome' consists of a burning sensation with a clinically normal oral mucosa. It occurs more commonly in middle-aged and elderly females. It is probably psychogenic in origin. *Halitosis* (bad breath) is a common symptom and is due to poor oral hygiene, anxiety (often when halitosis is more apparent to the patient than real) and rarer causes, e.g. oesophageal stricture and pulmonary sepsis.

Dyspepsia and indigestion

'Indigestion' is common: 80% of the population will suffer from this symptom at some time. Dyspepsia is an inexact term used to describe a number of upper abdominal symptoms such as heartburn, acidity, pain or discomfort, nausea, wind, fullness or belching. Patients, when using the term 'indigestion', may also be describing lower GI symptoms such as constipation or the presence of undigested vegetable material in the stool, so obtaining a precise history is necessary.

Features of dyspepsia suggestive of serious diseases such as cancer are known as 'Alarm' symptoms.

They include:

- Dysphagia
- Weight loss
- Vomiting
- Anorexia
- Haematemesis or melaena.

Patients with these features have a higher possibility of significant gastrointestinal pathology and should be investigated, although the benefits are small.

FURTHER READING

Vakil N, Moayyedi P, Fennerty MB et al. Limited value of alarm features in the diagnosis of upper gastrointestinal malignancy: systematic review and meta-analysis. *Gastroenterology* 2006; 131: 390-401.

Figure 6.1 Relative contribution of GI sites to all cancers.

Table 6.1 Causes of vomiting: some examples

Any gastrointestinal disease	Diabetic ketoacidosis
Infections	Drugs
Viruses (influenza, norovirus)	Antibiotics
Bacterial (pertussis, urinary infection)	Chemotherapy
Central nervous system disease	Digoxin
Raised intracranial pressure	Immunosuppressives such as azathioprine
Vestibular disturbance, e.g. motion sickness	Levodopa
Migraine	Opiates
Metabolic	Reflex
Uraemia	Myocardial infarction
Hypercalcaemia	Biliary colic
	Psychogenic
	Pregnancy
	Alcohol excess

Dysphagia and odynophagia

These symptoms are described on page 237.

Vomiting

Many gastrointestinal (and non-gastrointestinal) conditions are associated with vomiting (Table 6.1). This is controlled by a complex reflex involving central neural control centres located in the lateral reticular formation of the medulla which are stimulated by the chemoreceptor trigger zones (CTZs) in the floor of the fourth ventricle, and also by vagal afferents from the gut. The central zones are directly stimulated by toxins, drugs, motion sickness and metabolic disturbances. Raised intracranial pressure has a direct effect on the vomiting centre leading to vomiting. Luminal toxins, inflammation and mechanical obstruction are local GI causes of vomiting.

Nausea is a feeling of wanting to vomit, often associated with autonomic effects including salivation, pallor and sweating. It often precedes actual vomiting. Retching is a strong involuntary unproductive effort to vomit associated with abdominal muscle contraction but without expulsion of gastric contents through the mouth.

Faeculent vomit suggests low intestinal obstruction or the presence of a gastrocolic fistula.

Haematemesis is vomiting fresh or altered blood ('coffee-ground') (see p. 254).

Early-morning nausea and vomiting is seen in pregnancy, alcohol dependence and some metabolic disorders (e.g. uraemia).

Persistent nausea alone is often stress-related and is not due to gastrointestinal disease.

Flatulence

This term describes excessive wind. It is used to indicate belching, abdominal distension, gurgling and the passage of flatus per rectum. Swallowing air (aerophagia) is described on page 296. Some of the swallowed air passes into the intestine where most of it is absorbed, but some remains to be passed rectally. Colonic bacterial breakdown of non-absorbed carbohydrate also produces gas. Rectal flatus thus consists of nitrogen, carbon dioxide, hydrogen and methane. It is normal to pass rectal flatus up to 20 times/day. Causes of increased gas production and intake include high-fibre diet and carbonated drinks.

Diarrhoea and constipation

These are common complaints and in the community are not usually due to serious disease. They are described in detail on pages 291 and 282, respectively. Some general rules concerning the aetiology and investigation of diarrhoea are shown in Box 6.1.

Patients often consider themselves constipated if their bowels are not open on most days, though normal stool frequency is very variable, from 3 times daily to 3 times a week. The difficult passage of hard stool is also regarded as constipation, irrespective of stool frequency. Constipation with hard stools is rarely due to organic colonic disease.

Abdominal pain

Pain is stimulated mainly by the stretching of smooth muscle or organ capsules. Severe acute abdominal pain can be due to a large number of gastrointestinal conditions, and normally presents as an emergency (see p. 298). An apparent 'acute abdomen' can occasionally be due to referred pain from the chest, as in pneumonia or to metabolic causes, such as diabetic ketoacidosis or porphyria.

Check:

- Site (Fig. 6.2), intensity, character, duration and frequency of the pain
- Aggravating and relieving factors
- Associated symptoms, including non-gastrointestinal symptoms.

Upper abdominal pain

Epigastric pain is very common and is often related to food intake. Although functional dyspepsia is the commonest diagnosis, the symptoms of peptic ulcer disease can be identical. **Heartburn** (a burning pain behind the sternum) is a common symptom of gastro-oesophageal reflux.

Right hypochondrial pain may originate from the gall bladder or biliary tract. Biliary pain can also be epigastric. **Biliary pain** is typically intermittent and severe, lasts a few hours and remits spontaneously to recur weeks or months

Box 6.1 Simple rules in diarrhoea

- A single episode of diarrhoea is commonly due to dietary indiscretion or anxiety.
- Large volume watery stools always have an organic cause.
- Bloody diarrhoea implies colonic and/or rectal disease.
- Acute diarrhoea lasting 2–5 days is most often due to an infective cause.
 - Stool cultures should be taken to exclude an infective cause.

Figure 6.2 The abdominal quadrants.

later. Hepatic congestion (e.g. in hepatitis or cardiac failure) and sometimes peptic ulcer disease can present with pain in the right hypochondrium. Chronic, persistent or constant pain in the right (or left) hypochondrium in a well-looking patient is a frequent functional symptom; this chronic pain is not due to gall bladder disease (see p. 353).

Lower abdominal pain

Pain in the left iliac fossa may be colonic in origin (e.g. acute diverticulitis) but chronic pain is most commonly associated with functional bowel disorders.

Lower abdominal pain in women occurs in a number of gynaecological disorders and the differentiation from GI disease may be difficult.

Pain in the right iliac fossa may be due to acute appendicitis or ileocaecal disease, but may also commonly be functional.

Proctalgia fugax is a severe pain deep in the rectum that comes on suddenly but lasts only for a short time. It is not due to organic disease.

Abdominal wall pain

Persistent abdominal pain with localized tenderness, which is not relieved by tensing the abdominal muscles, is probably from the abdominal wall itself. Causes are thought to include nerve entrapment, external hernias, and entrapment of internal viscera (commonly omentum) within traumatic or surgical alterations of abdominal wall musculature.

Anorexia and weight loss

Anorexia describes reduced appetite. It is common in systemic disease and may be seen in psychiatric disorders. Anorexia often accompanies cancer but is usually a late symptom and not of diagnostic help. Weight loss is almost always due to reduced food intake and is a frequent accompaniment of gastrointestinal diseases. Weight loss in malabsorption disorders is primarily due to anorexia. Weight loss with a normal or increased dietary intake only occurs with hyperthyroidism and other catabolic states. Weight loss should always be assessed objectively as patients' impressions are unreliable.

Figure 6.3 The organs sometimes palpable in thin subjects.

Examination of the abdomen

Inspection

Look for abdominal distension. Common causes (the five Fs) are: flatus, fat, fetus, fluid and faeces. Intermittent distension is most commonly a feature of functional bowel disorders.

Palpation

Look for palpable masses or abdominal tenderness. All abdominal quadrants should be palpated in turn followed by deeper palpations; remember to watch the patient's face for signs of pain or discomfort. Evaluate any palpable mass and note its size, shape and consistency and whether it moves with respiration, to decide which organ is involved. Some abdominal organs may be just palpable normally, usually in thin people (Fig. 6.3). Reidel's lobe is an anatomical variant consisting of a palpable enlargement of the lateral portion of the right lobe of the liver. The hernial orifices should be examined if intestinal obstruction is suspected.

Percussion

Abdominal percussion detects the areas of dullness caused by the liver and spleen, ascites or over masses. It can also detect a full bladder. *Ascites* is a term for excess fluid in the peritoneal cavity. It is detected clinically by central abdominal resonance due to gas within small bowel loops with dullness in the flanks which shifts when the patient lies on their side. This 'shifting dullness' is a reliable physical sign, if 1–2 L of fluid are present.

Auscultation

Auscultation is not of great value in abdominal disease, except for evaluation of bowel sounds in the acute abdomen (see p. 299). Abdominal bruits are often present in normal subjects and are rarely clinically significant.

A succussion splash suggests gastric outlet obstruction if the patient has not drunk for 2–3 hours. The splash of fluid in the stomach can be heard with a stethoscope laid on the abdomen when the patient is moved.

Examination of the rectum and sigmoid colon

A digital examination of the rectum should be performed in all patients with a change in bowel habit, rectal bleeding and prior to proctoscopy or sigmoidoscopy.

- **Proctoscopy** (see Practical Box 6.1) is performed in all patients with a history of bright red rectal bleeding to look for anorectal pathology such as haemorrhoids; a rigid sigmoidoscope is too narrow and long to enable adequate examination of the anal canal.

Introduction

Gastrointestinal symptoms and signs

Practical Box 6.1

Sigmoidoscopy and proctoscopy

Sigmoidoscopy

- The technique using a 25 cm rigid sigmoidoscope is easy to learn, provides valuable information and is safe in competent hands.
- No bowel preparation is required.
- Explain to the patient the nature of the procedure and obtain consent.
- The technique is relatively painless. In the irritable bowel syndrome, the patient's pain is often reproduced by air insufflation:
 1. Rectal examination is initially performed.
 2. The sigmoidoscope is passed into the anus, pointing towards the symphysis pubis. The obturator is removed, and the instrument passed under direct vision to the rectosigmoid junction and beyond if possible (using air insufflation).
 3. The mucosa of the anus and rectum is inspected. The normal mucosa is shiny with superficial vessels and no contact bleeding.

Proctoscopy

1. The proctoscope is passed into the anus and the obturator is removed.
2. The patient strains down as the proctoscope is removed.
3. Haemorrhoids are seen as purplish veins in the left lateral, right posterior or right anterior positions.
4. Fissures may also be seen, but pain often prevents the procedure from being performed.

- **Sigmoidoscopy** is part of the routine hospital examination in cases of diarrhoea and in patients with lower abdominal symptoms such as a change in bowel habit or rectal bleeding. The rigid sigmoidoscope allows inspection of a maximum of 20–25 cm of distal colon.
- **Flexible sigmoidoscopy (FS)** (60 cm) can reach up to the splenic flexure, and can be performed in the outpatient department or endoscopy unit after evacuation of the distal colon using an enema or suppository. FS can be used in patients with increased stool frequency or looseness or rectal bleeding to diagnose colitis or polyps. Most rectal bleeding is due to benign anorectal disease (haemorrhoids or fissure-in-ano) and an otherwise normal FS can be reassuring to avoid over-investigation. Up to 60% of colonic neoplasms occur within the range of FS (see Fig. 6.45) and it has therefore been proposed as screening test for colorectal cancer in asymptomatic individuals.

Stool examination

It is useful to confirm a patient's account (e.g. passing of blood or steatorrhoea). The shape and size may be helpful (e.g. 'rabbit dropping' or ribbon-like stools in the irritable bowel syndrome). Stool charts for recording consistency and frequency of defecation are useful in inpatients to follow the progress of diarrhoea, particularly in the management of severe colitis. The Bristol Stool Chart is commonly used in the UK (Fig. 6.4).

INVESTIGATIONS

Routine haematology and biochemistry, followed by endoscopy and radiology, are the principal investigations. The

Figure 6.4 The Bristol Stool Chart. (Reproduced by kind permission of Dr K W Heaton, Reader in Medicine at the University of Bristol. © 2000 Norgine Pharmaceuticals Ltd.)

investigation of small bowel disease is discussed in more detail on page 267. Manometry is mainly used in oesophageal disease (see p. 237) and anorectal disorders (see p. 286).

Endoscopy

Video endoscopes have replaced fiberoptic instruments and relay colour images to a high definition television monitor. The tip of the endoscope can be angulated in all directions. Channels in the instrument are used for air insufflation, water injection, suction, and for the passage of accessories such as biopsy forceps or brushes for obtaining tissue, snares for polypectomy and needles for injection therapies. Permanent photographic or video records of the procedure can be obtained.

- **Oesophagogastroduodenoscopy (OGD, 'gastroscopy')** is the investigation of choice for upper GI disorders with the possibility of therapy and mucosal biopsy. Findings include reflux oesophagitis, gastritis, ulcers and cancer. Therapeutic OGD is used to treat upper GI haemorrhage and both benign and malignant obstruction. Relative contraindications include severe chronic obstructive pulmonary disease, a recent myocardial infarction, or severe instability of the atlantoaxial joints. The mortality for diagnostic endoscopy is 0.001% with significant complications in 1:10000, usually when performed as an emergency (e.g. GI haemorrhage).
- **Colonoscopy** allows good visualization of the whole colon and terminal ileum. Biopsies can be obtained and polyps removed. Benign strictures can be dilated and malignant strictures stented. The success rate for reaching the caecum should be at least 90% after training. Cancer, polyps and diverticular disease are the

Practical Box 6.2

Gastroscopy and colonoscopy

- Explain the procedure to the patient, including benefits and risks.
- Discuss the need for sedation.
- Obtain written informed consent.

Gastroscopy

1. Patient should be fasted for at least 4 hours.
2. Give oxygen and monitor oxygen saturation with an oximeter.
3. Give lidocaine throat spray or sedation (midazolam \pm opiate if required).
4. Pass the gastroscope to the duodenum under direct vision.
5. Examine during insertion and withdrawal.
6. Gastroscopy takes 5–15 min, depending on the indication and findings.
7. Withhold fluid and food until LA/sedation wears off.
8. Complications are rare: beware of over-sedation, perforation and aspiration.
9. Patient must be accompanied home if sedation given.

Colonoscopy

1. Stop oral iron a week before the procedure.
2. Restrict diet to low residue foods for 48 hours; clear fluids only for 24 hours.
3. Use local bowel cleansing regime, usually starting 24 hours beforehand (e.g. two sachets of sodium picosulfate with magnesium citrate and 2–4 bisacodyl tablets, or macrogols 2–4 L, or local alternative; more if constipated).
4. Give oxygen and monitor O₂ levels.
5. Give sedation (midazolam \pm opiate) if required by patient.
6. Pass the colonoscope to the caecum or ileum under direct vision.
7. Examine in detail during withdrawal.
8. Colonoscopy takes 15–30 min, depending on the colon anatomy, indication and findings.
9. Withhold fluid and food until sedation wears off.
10. Observe patient for at least an hour after sedation given.
11. Complications are rare: beware of over-sedation, perforation and aspiration.
12. Patient must be accompanied home if sedation given.

commonest significant findings. Perforation occurs in 1:1000 examinations but this is higher (up to 2%) after polypectomy (see [Practical Box 6.2](#)).

- **Balloon enteroscopy**, either double or single balloon, can examine the small bowel from the duodenum to the ileum using specialized enteroscopes in expert centres.
- **Capsule endoscopy** is used for the evaluation of obscure GI bleeding (after negative gastroscopy and colonoscopy) and for the detection of small bowel tumours and occult inflammatory bowel disease. It should be avoided if strictures are suspected.

Imaging

Full clinical information must be provided before the examination, and ideally, the images obtained should be reviewed with the radiologist to aid interpretation. The optimal technique to be used will depend on local expertise.

Plain X-rays of the chest and abdomen are chiefly used in the investigation of an acute abdomen. Interpretation depends on analysis of gas shadows inside and outside the bowel. Plain films are particularly useful where obstruction or perforation is suspected, to exclude toxic megacolon in

colitis and to assess faecal loading in constipation. Calcification may be seen with gall bladder stones and in chronic pancreatitis, though CT is more sensitive for both.

Ultrasound involves no radiation and is the first-line investigation for abdominal distension, e.g. ascites, mass or suspected inflammatory conditions. It can show dilated fluid-filled loops of bowel in obstruction, and thickening of the bowel wall. It can be used to guide biopsies or percutaneous drainage. In an acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands and other inflammatory conditions.

- **Endoscopic ultrasound (EUS)** is performed with a gastroscope incorporating an ultrasound probe at the tip. It is used diagnostically for lesions in the oesophageal or gastric wall, including the detailed TNM staging (see [p. 245](#)) of oesophageal/gastric cancer and for the detection and biopsy of pancreatic tumours and cysts.
- **Endoanal and endorectal ultrasonography** are performed to define the anatomy of the anal sphincters (see [p. 285](#)), to detect perianal disease and to stage superficial rectal tumours.

Computed tomography involves a significant dose of radiation (approximately 10 millisieverts). Modern multislice fast scanners and techniques involving intraluminal and intravenous contrast enhance diagnostic capability. Intraluminal contrast may be positive (Gastrografin or Omnipaque) or negative (usually water). The bowel wall and mesentery are well seen after intravenous contrast especially with negative intraluminal contrast. Clinically unsuspected diseases of other abdominal organs are quite often also revealed ([Fig. 6.5a](#)).

- CT is widely used as a first-line investigation for the acute abdomen. CT is sensitive for small volumes of gas from a perforated viscus as well as leakage of contrast from the gut lumen.
- Inflammatory conditions such as abscesses, appendicitis, diverticulitis, Crohn's disease and its complications are well demonstrated. In high-grade bowel obstruction, CT is usually diagnostic of both the presence and the cause of the obstruction.
- CT is widely used in cancer staging and as guidance for biopsy of tumour or lymph nodes.
- **CT pneumocolon/CT colonography** (virtual colonoscopy) after CO₂ insufflation into a previously cleansed colon provides an alternative to colonoscopy for diagnosis of colon mass lesions ([Fig. 6.5b](#)). It is being evaluated as a screening test for colon pathology with sensitivities of over 90% for >10 mm polyps.
- **Unprepared CT** is a good test for colon cancer in the frail (often elderly) patient who would have problems with bowel preparation.

Magnetic resonance imaging. MRI uses no radiation and is particularly useful in the evaluation of rectal cancers and abscesses and fistulae in the perianal region. It is also useful in small bowel disease and in hepatobiliary and pancreatic disease.

Positron emission tomography (PET) relies on detection of the metabolism of fluorodeoxyglucose. It is used for staging oesophageal, gastric and colorectal cancer and in the detection of metastatic and recurrent disease. PET/CT adds additional anatomical information.

Contrast studies

- **Barium swallow** examines the oesophagus and proximal stomach. Its main use is for investigating dysphagia.

a

b

c

Figure 6.5 (a) CT scan of the normal abdomen at the level of T12. (1) Aorta; (2) spine; (3) top of right kidney; (4) liver; (5) gall bladder; (6) stomach (containing air); (7) pancreas; (8) spleen.

(b) CT cross-sectional (2-dimensional) image of a colonic polyp on a long stalk. The colon has been emptied as for visual colonoscopy. The pedunculated polyp and its stalk show enhancement after intravenous contrast.

(c) 3D reconstruction of part of the colon (false colour) generated by a computer program from multiple axial CT images. A sessile polypoid lesion is shown. (b and c: Courtesy of Dr Paul Jenkins.)

- **Double-contrast barium meal** examines the oesophagus, stomach and duodenum. Barium is given to produce mucosal coating and effervescent granules producing carbon dioxide in the stomach create a double contrast between gas and barium. This test has a high accuracy for the detection of significant pathology – ulcers and cancer – but requires good technique. Gastroscopy is a more sensitive test and enables biopsy of suspicious areas.
- **Small bowel meal or follow-through** specifically examines the small bowel. Ingested barium passes through the small bowel into the right colon. The fold pattern and calibre of the small bowel are assessed. Specific views of the terminal ileum can be obtained

and are used to identify early changes in patients with suspected Crohn's disease.

- **Small bowel enema (enteroclysis)** is an alternative specific technique for small bowel examination. A tube is passed into the duodenum and a large volume of dilute barium is introduced. It is particularly used to demonstrate strictures or adhesions when there is suspicion of intermittent obstruction. Generally, this has been replaced by MR enteroclysis.
- **Barium enema** examines the colon and is used for altered bowel habit. Colonoscopy and CT colonography have largely replaced this examination for rectal bleeding, polyps and inflammatory bowel disease.
- **Absorbable water-soluble (Gastrografin or Omnipaque) contrast agents** should be used in preference to barium when perforation is suspected anywhere in the gut.

Radioisotopes

Radionuclides are used to a varying degree depending on availability and expertise. Some more common indications and techniques:

- Detect urease activity of *Helicobacter pylori* – ^{13}C urea breath test (see p. 249)
- Assess oesophageal reflux – gamma camera scan after oral $^{99\text{m}}\text{Tc}$ technetium-sulphur colloid
- Measure rate of gastric emptying – sequential gamma camera scans after oral $^{99\text{m}}\text{Tc}$ technetium-sulphur colloid or ^{111}In -DTPA (indium-labelled diethylene triamine penta-acetic acid)
- Demonstrate a Meckel's diverticulum – gamma camera scan after i.v. $^{99\text{m}}\text{Tc}$ pertechnetate, which has affinity for gastric mucosa
- Assess extent of inflammation and presence of inflammatory collections in inflammatory bowel disease – gamma camera scan after i.v. $^{99\text{m}}\text{Tc}$ -HMPAO (hexamethylpropylene amine oxime) labelled white cells
- Evaluate neuroendocrine tumours and their metastases – gamma camera scan after i.v. radiolabelled octreotide or MIBG (meta-iodobenzylguanidine)
- Assess obscure gastrointestinal bleeding – gamma camera abdominal scan after i.v. injection of red cells labelled with $^{99\text{m}}\text{Tc}$ (only useful if the bleeding is $>2\text{ mL/min}$)
- Measure albumin loss in the stools (in *protein-losing enteropathy*) – following albumin labelled *in vivo* with i.v. $^{51}\text{CrCl}_3$. This test has been replaced by the measurement of the intestinal clearance of α_1 antitrypsin
- Assess bile salt malabsorption (in patients with unexplained diarrhoea) – gamma camera scan to measure both isotope retention and faecal loss of orally administered ^{75}Se selenium-homocholic acid taurine (SeHCAT) (see p. 293)
- Detect bacterial overgrowth in the small bowel – measure $^{14}\text{CO}_2$ in breath following oral ^{14}C glycocholic acid.

THE MOUTH

The oral cavity extends from the lips to the pharynx and contains the tongue, teeth and gums. Its primary functions

are mastication, swallowing and speech. Problems in the mouth are extremely common and, although they may be trivial, they can produce severe symptoms. Poor dental hygiene is often a factor.

Recurrent aphthous ulceration

Idiopathic aphthous ulceration is common and affects up to 25% of the population. Recurrent painful round or ovoid mouth ulcers are seen with inflammatory halos. They are commoner in females and non-smokers, usually appear first in childhood and tend to reduce in number and frequency before age 40. Other family members may be affected. There is no sign of systemic disease.

- **Minor aphthous ulcers** are the most common, are <10 mm diameter, have a grey/white centre with a thin erythematous halo and heal within 14 days without scarring. They rarely affect the dorsum of the tongue or hard palate.
- **Major aphthous ulcers** (>10 mm diameter) often persist for weeks or months and heal with scarring.

The cause is not known. Deficiencies of iron, folic acid or vitamin B₁₂ (with or without gastrointestinal disorders) are sometimes found but are not causally linked. Secondary causes, e.g. Crohn's disease, should be excluded.

There are no specific effective therapies. Sufferers should avoid oral trauma and acidic foods or drinks which cause pain. Topical (1% triamcinolone) or systemic corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate or tetracycline mouthwash, dapsone, colchicine, thalidomide and azathioprine have all been used with variable effect.

Other causes

See Table 6.2.

Neoplasia (squamous cell carcinoma)

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The majority develop on the floor of the mouth or lateral borders of the tongue. Early lesions may be painless, but advanced tumours are easily recognizable as hard indurated ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption and the areca nut. Human papillomavirus 16 causes some oral cancers. Premalignant lesions include leucoplakia (single adherent white patch), lichen planus, submucous fibrosis and erythroplakia (a red patch).

Treatment is by surgical excision which may require extensive neck dissection to remove involved lymph nodes and/or radiotherapy. Ablative treatment with photodynamic therapy is being pioneered for early lesions.

Oral white patches

Transient white patches are either due to *Candida* infection or are very occasionally seen in systemic lupus erythematosus. Local causes include mechanical, irritative or chemical trauma from drugs (e.g. ill fitting dentures or aspirin). Oral candidiasis in adults is seen following therapy with broad-spectrum antibiotics or inhaled steroids and in people with diabetes, patients who are seriously ill or immunocompromised.

Persistent white patches can be due to *leucoplakia*, which is associated with alcohol and (particularly) smoking, and is premalignant. A biopsy should always be taken; histology shows alteration in the keratinization and dysplasia of the epithelium. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. *Oral lichen planus* presents as white striae, which can rarely extend into the oesophagus.

Oral pigmented lesions

Non-neoplastic lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral pigmentation and consists of blue-black macules involving the gingivae and results from dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz-Jeghers syndrome and Addison's disease. Heavy metals, such as lead, bismuth and mercury, and drugs (e.g. phenothiazines and antimalarials) all cause pigmentation of the gums.

Neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, more common in males and occur mainly on the upper jaw. The 5-year survival is only 5%.

The tongue

The tongue may be affected by inflammatory or malignant processes with similar lesions to those described above.

- **Glossitis** is a red, smooth, sore tongue associated with B₁₂, folate or iron deficiency. It is also seen in infections due to *Candida* and in riboflavin and nicotinic acid deficiency.
- **A black hairy tongue** is due to a proliferation of chromogenic microorganisms causing brown staining of elongated filiform papillae. The causes are unknown, but heavy smoking and the use of antiseptic mouthwashes have been implicated.
- **A geographic tongue** is an idiopathic condition occurring in 1–2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins. The lesions are usually painless and the patient should be reassured.

The gums

The gums (gingivae) are the mucous membranes covering the alveolar processes of the mandible and the maxilla.

- **Chronic gingivitis** follows the accumulation of bacterial plaque. It resolves when the plaque is removed. It is the most common cause of bleeding gums.

Table 6.2 Causes of mouth ulcers

Idiopathic aphthous ulceration (commonest)	Trauma e.g. dentures
Gastrointestinal disease	Neoplasia e.g. squamous cell carcinoma
Inflammatory bowel disease	
Coeliac disease	Drugs In erythema multiforme major, toxic epidermal necrolysis
Infection	Chemotherapy, antimalarials
Viral – HSV, HIV, Coxsackie	Skin disease Pemphigoid
Fungal – candidiasis	Pemphigus
Bacterial – syphilis, tuberculosis	Lichen planus
Systemic disease	
Reactive arthritis (see p. 529)	
Behçet's syndrome	
Systemic lupus erythematosus	

- **Acute (necrotizing) ulcerative gingivitis** ('Vincent's angina') is characterized by the proliferation of spirochaete and fusiform bacteria associated with poor oral hygiene and smoking. Treatment is with oral metronidazole 200 mg three times daily for 3 days, improved oral hygiene and chlorhexidine gluconate mouthwash.
- **Desquamative gingivitis** is a clinical description of smooth, red atrophic gingivae caused by lichen planus or mucous membrane pemphigoid. The diagnosis is confirmed by biopsy.
- **Gingival swelling** may be due to inflammation or fibrous hyperplasia. The latter may be hereditary (gingival fibromatosis) or associated with drugs (e.g. phenytoin, ciclosporin, nifedipine). Inflammatory swellings are seen in pregnancy, gingivitis and scurvy. Swelling due to infiltration is seen in acute leukaemia and Wegener's granulomatosis.

The teeth

Dental caries occur as a result of bacterial damage to tooth structures leading to tooth decay and 'cavities'. The main cause in man is *Streptococcus mutans*, which is cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dentoalveolar abscesses. If there is soft tissue swelling, antibiotics (e.g. amoxicillin or metronidazole) should be prescribed prior to dental intervention.

Erosion of the teeth can result from exposure to acid (e.g. in bulimia nervosa) or, very occasionally, in patients with gastro-oesophageal reflux disease.

Oral manifestations of HIV infection

HIV-infected patients often have characteristic oral lesions. Lesions strongly associated with HIV infection include candidiasis (with erythema and/or white exudates), erythematous candidiasis, oral hairy leucoplakia, Kaposi's sarcoma, non-Hodgkin's lymphoma, necrotizing ulcerative gingivitis and necrotizing ulcerative periodontitis and are described elsewhere.

All oral lesions are much less common since the introduction of HAART (in Chapter 4).

THE SALIVARY GLANDS

Excessive salivation (ptyalism) may occur prior to vomiting or be secondary to other intraoral pathology. It can be psychogenic.

Dry mouth (xerostomia) can result from a variety of causes:

- Sjögren's syndrome
- Drugs (e.g. antimuscarinic, antiparkinsonian, antihistamines, lithium, monoamine oxidase inhibitors, tricyclic and related antidepressants, and clonidine)
- Radiotherapy
- Psychogenic
- Dehydration, shock and chronic kidney disease.

The principles of management are to preserve what flow remains, stimulate flow and replace saliva (glycerine and lemon mouthwash and artificial saliva).

Sialadenitis

Acute sialadenitis is viral (mumps, p. 110) or bacterial. Bacterial sialadenitis is a painful ascending infection with

Staphylococcus aureus, *Streptococcus pyogenes* and *Strep. pneumoniae*, usually secondary to secretory failure. Pus can be expressed from the affected duct.

Salivary duct obstruction due to calculus

Obstruction to salivary flow is usually due to a calculus. There is a painful swelling of the submandibular gland after eating and stones can sometimes be felt in the floor of the mouth. Plain X-ray films and sialography will show the calculus; removal of the obstruction by sialoendoscopy gives complete relief.

Sarcoidosis (see also p. 845)

Sarcoidosis can involve the major salivary glands as part of *Heerfordt's syndrome* (uveoparotid fever).

Neoplasms

Salivary gland neoplasms account for 3% of all tumours worldwide. The majority occur in the parotid gland. The pleomorphic adenoma is the most common and 15% of these undergo malignant transformation. Malignant tumours classically result in lower motor neurone 7th cranial nerve signs. Recurrence following surgical excision is common.

THE PHARYNX AND OESOPHAGUS

Structure and physiology

The oesophagus is a muscular tube approximately 20 cm long that connects the pharynx to the stomach just below the diaphragm. Its only function is to transport food from the mouth to the stomach. In the upper portion of the oesophagus, both the outer longitudinal layer and inner circular muscle layers are striated. In the lower two-thirds of the oesophagus, including the thoracic and abdominal parts containing the lower oesophageal sphincter, both layers are composed of smooth muscle.

The oesophagus is lined by stratified squamous epithelium, which extends distally to the squamocolumnar junction where the oesophagus joins the stomach, recognized endoscopically by a zig-zag ('Z') line, just above the most proximal gastric folds.

The oesophagus is separated from the pharynx by the *upper oesophageal sphincter* (UOS), which is normally closed due to tonic activity of the nerves supplying the cricopharyngeus. The *lower oesophageal sphincter* (LOS) consists of a 2–4 cm zone in the distal end of the oesophagus that has a high resting tone and, assisted by the diaphragmatic sphincter, is largely responsible for the prevention of gastric reflux.

Swallowing

During swallowing, the bolus of food is voluntarily moved from the mouth to the pharynx. This process is mediated by a complex reflex involving a swallowing centre in the dorsal motor nucleus of the vagus in the brainstem. Once activated, the swallowing centre neurones send pre-programmed discharges of inhibition followed by excitation to the motor nuclei of the cranial nerves. This results in initial relaxation, followed by distally progressive activation of neurones to the oesophageal smooth muscle and LOS. Pharyngeal and

Figure 6.6 Innervation of the oesophagus. The *excitatory pathway* consists of vagal preganglionic neurones releasing acetylcholine (ACh), connecting to postganglionic neurones that release ACh and substance P. The *inhibitory pathway* consists of vagal preganglionic neurones releasing ACh, connecting to postganglionic neurones that release nitric oxide (NO), vasoactive intestinal peptide (VIP), adenosine triphosphate (ATP) and substance P (SP).

oesophageal peristalsis mediated by this swallowing reflex causes *primary peristalsis*. *Secondary peristalsis* arises as a result of stimulation by a food bolus in the lumen, mediated by a local intra-oesophageal reflex. *Tertiary contractions* indicate pathological non-propulsive contractions resulting from aberrant activation of local reflexes within the myenteric plexus.

The smooth muscle of the thoracic oesophagus and lower oesophageal sphincter is supplied by vagal autonomic motor nerves consisting of extrinsic preganglionic fibres and intra-mural postganglionic neurones in the myenteric plexus (Fig. 6.6). There are parallel excitatory and inhibitory pathways.

Symptoms of oesophageal disorders

Major oesophageal symptoms are:

- **Dysphagia**, or difficulty in swallowing, is defined as a sensation of obstruction during the passage of liquid or solid through the pharynx or oesophagus, i.e. within 15 s of food leaving the mouth. The characteristics of the progression of dysphagia to solids can be helpful, e.g. intermittent slow progression with a history of heartburn suggests a benign peptic stricture; relentless progression over a few weeks suggests a malignant stricture. The slow onset of dysphagia for solids and

Table 6.3 Causes of dysphagia

Disease of mouth and tongue e.g. tonsillitis	Extrinsic pressure Mediastinal glands Goitre Enlarged left atrium

liquids at the same time suggests a motility disorder, e.g. achalasia (see p. 237). The causes are shown in Table 6.3.

- **Odynophagia** is pain during the act of swallowing and is suggestive of oesophagitis. Causes include reflux, infection, chemical oesophagitis due to drugs such as bisphosphonates or slow-release potassium or associated with oesophageal stenosis.
- **Substernal discomfort, heartburn.** This is a common symptom of reflux of gastric contents into the oesophagus. It is usually a retrosternal burning pain that can spread to the neck, across the chest, and when severe can be difficult to distinguish from the pain of ischaemic heart disease. It is often worst lying down at night when gravity promotes reflux or on bending or stooping.
- **Regurgitation** is the effortless reflux of oesophageal contents into the mouth and pharynx. Uncommon in normal subjects, it occurs frequently in patients with gastro-oesophageal reflux disease or organic stenosis.

Signs of oesophageal disorders

The main sign of oesophageal disease is weight loss due to reduced food intake. Cervical lymphadenopathy with cancer is uncommon. Rarely a pharyngeal pouch may be seen to swell the neck during drinking.

Investigations available for oesophageal disorders

- **Barium swallow and meal.**
- **Oesophagoscopy.**
- **Manometry** (Fig. 6.7) is performed by passing a catheter through the nose into the oesophagus and measuring the pressures generated within the oesophagus. It is used to assess oesophageal motor activity. It is not a primary investigation and should be performed only when the diagnosis has not been achieved by history, barium radiology or endoscopy. Recordings are usually made over a short time period, or much more rarely for up to 24 h. High resolution manometry has superseded conventional manometry and the greater concentration of pressure sensors enables the identification of a wider range of abnormalities of oesophageal function with a greater diagnostic accuracy.
- **pH monitoring** – 24-hour ambulatory monitoring uses a pH-sensitive probe positioned in the lower oesophagus

The salivary glands

The pharynx and oesophagus

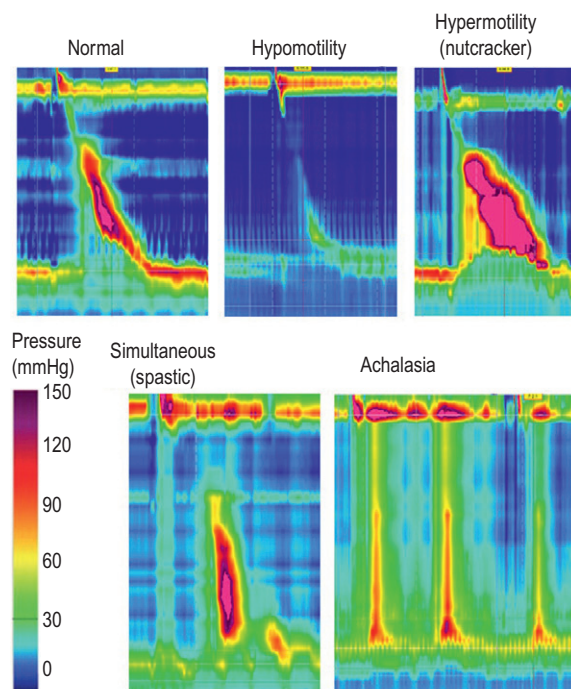

Figure 6.7 High resolution manometry of the oesophagus in the normal subject and in patients with hypomotility, hypermotility, simultaneous (spastic) contractions and achalasia. Changes in colour reflect changes in pressure.

and is used to identify acid reflux episodes (pH <4). Catheter and implantable sensors are available; both are insensitive to alkali. Although only 5–10% of recorded acid reflux episodes are perceived by the patient, pH is a valuable means of correlating episodes of acid reflux with patient's symptoms.

- **Impedance** uses a catheter to measure the resistance to flow of 'alternating current' in the contents of the oesophagus. Combined with pH it allows assessment of acid, weakly acid, alkaline and gaseous reflux, which is helpful in understanding the symptoms that are produced by a non-acid reflux. Treatment is, however, still difficult in these conditions.

Gastro-oesophageal reflux disease (GORD)

Pathophysiology

Between swallows, the muscles of the oesophagus are relaxed except for those of the sphincters. The LOS remains closed due to the unique property of the muscle and relaxes when swallowing is initiated. Transient Lower Oesophageal Sphincter Relaxations (TLESRs) are part of normal physiology, but occur more frequently in GORD patients (Fig. 6.8).

Small amounts of gastro-oesophageal reflux are normal. The lower oesophageal sphincter (LOS) in the distal oesophagus is in a state of tonic contraction and relaxes transiently to allow the passage of a food bolus (see p. 229). Sphincter pressure also increases in response to rises in intra-abdominal and intra-gastric pressures.

Other antireflux mechanisms involve the intra-abdominal segment of the oesophagus which acts as a flap valve. In addition, the mucosal rosette formed by folds of the gastric mucosa and the contraction of the crural diaphragm at the LOS acting like a pinchcock, prevent acid reflux. A large hiatus hernia can impair this mechanism. The oesophagus is

Figure 6.8 The main antireflux mechanisms – shown on the right.

Table 6.4 Factors associated with gastro-oesophageal reflux

also normally rapidly 'cleared' of refluxate by secondary peristalsis, gravity and salivary bicarbonate.

The clinical features of reflux occur when the antireflux mechanisms fail, allowing acidic gastric contents to make prolonged contact with the lower oesophageal mucosa. The sphincter relaxes transiently independently of a swallow after meals and this is the cause of almost all reflux in normals and about two-thirds in GORD patients.

Oesophageal mucosal defence mechanisms

- **Surface.** Mucus and the unstirred water layer trap bicarbonate. This mechanism is a weak buffering mechanism compared to that in the stomach and duodenum.
- **Epithelium.** The apical cell membranes and the junctional complexes between cells act to limit diffusion of H^+ into the cells. In oesophagitis, the junctional complexes are damaged leading to increased H^+ diffusion and cellular damage.
- **Postepithelium.** Bicarbonate normally buffers acid in the cells and intracellular spaces. Hydrogen ions impair the growth and replication of damaged cells.
- **Sensory mechanisms.** Acid stimulates primary sensory neurones in the oesophagus by activating the vanilloid receptor-1 (VR1). This can initiate inflammation and release of pro-inflammatory substances from the tissue and produce pain. Pain can also be due to contraction of longitudinal oesophageal muscle.

Clinical features

Heartburn is the major feature. Factors associated with GORD are shown in Table 6.4.

The burning is aggravated by bending, stooping or lying down which promote acid exposure, and may be relieved by oral antacids. The patient complains of pain on drinking hot liquids or alcohol.

The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis but severe

Box 6.2 Hiatus hernia**Sliding hiatus hernia**

The oesophageal-gastro junction and part of the stomach 'slides' through the hiatus so that it lies above the diaphragm.

- Present in 30% of people over 50 years
- Produces no symptoms – any symptoms are due to reflux

Rolling or para-oesophageal hernia

Part of the fundus of the stomach prolapses through the hiatus alongside the oesophagus.

- The lower oesophageal sphincter remains below the diaphragm and remains competent
- Occasionally severe pain occurs due to volvulus or strangulation

Box 6.3 Features of the pain of gastro-oesophageal reflux and cardiac ischaemia**Reflux pain: burning, worse on bending, stooping or lying down**

- Seldom radiates to the arms
- Worse with hot drinks or alcohol
- Relieved by antacids

Cardiac ischaemic pain:

- Gripping or crushing
- Radiates to neck or left arm
- Worse with exercise
- Accompanied by dyspnoea

a

(b) Los Angeles Classification of oesophagitis. **Grade A** = mucosal breaks confined to the mucosal folds, each no longer than 5 mm. **Grade B** = at least one mucosal break longer than 5 mm confined to the mucosal fold but not continuous between two folds. **Grade C** = mucosal breaks that are continuous between the tops of mucosal folds but not circumferential. **Grade D** = extensive mucosal breaks engaging at least 75% of the oesophageal circumference.

heartburn; others have severe oesophagitis without symptoms, and may present with a haematemesis or iron deficiency anaemia from chronic blood loss. Psychosocial factors are often determinants of symptom severity. Many patients erroneously ascribe their symptoms to their hiatus hernia (Box 6.2) but the symptoms are due to reflux.

Differentiation of cardiac and oesophageal pain can be difficult; 20% of cases admitted to a coronary care unit have GORD (Box 6.3). In addition to the clinical features, a trial of a proton pump inhibitor (PPI) is always worthwhile and if symptoms persist, ambulatory pH and impedance monitoring should be performed.

Regurgitation of food and acid into the mouth occurs, particularly on bending or lying flat. Aspiration pneumonia

is unusual without an accompanying stricture, but cough and asthma can occur and respond slowly (1–4 months) to a PPI.

Diagnosis and investigations

The *clinical* diagnosis can usually be made without investigation. Unless there are alarm signs, especially dysphagia (see p. 229), patients under the age of 45 years can safely be treated initially without investigations. If investigation is required, there are two aims:

- **Assess oesophagitis and hiatal hernia by endoscopy.** If there is oesophagitis (Fig. 6.9) or Barrett's oesophagus (see p. 241), reflux is confirmed.

Figure 6.10 24-hour intraluminal pH monitoring. Five reflux episodes (pH <4) occurred, but only three gave symptoms (arrows).

- **Document reflux by intraluminal monitoring** (Fig. 6.10). 24-hour intraluminal pH monitoring or impedance combined with manometry is helpful if there is no response to PPI and should always be performed to confirm reflux before surgery. Excessive reflux is defined as a pH <4 for >4% of the time. There should also be a good correlation between reflux (pH <4.0) and symptoms. It is also helpful to assess oesophageal dysmotility as a potential cause of the symptoms.

Treatment

Approximately half of patients with reflux symptoms in primary care can be treated successfully with simple antacids, loss of weight and raising the head of the bed at night. Precipitating factors should be avoided, with dietary measures, reduction in alcohol and caffeine consumption and cessation of smoking. These measures are simple to say but difficult to carry out, though they are useful in mild disease in compliant patients.

Drugs

Alginate-containing antacids (10 mL three times daily) are the most frequently used 'over the counter' agents for GORD. They form a gel or 'foam raft' with gastric contents to reduce reflux. Magnesium-containing antacids tend to cause diarrhoea while aluminium-containing compounds may cause constipation.

The dopamine antagonist prokinetic agents metoclopramide and domperidone are occasionally helpful as they enhance peristalsis and speed gastric emptying, but there is little data to substantiate this.

H₂-receptor antagonists (e.g. cimetidine, ranitidine, famotidine and nizatidine) are frequently used for acid suppression if antacids fail as they can often be obtained over the counter.

Proton pump inhibitors (PPIs: omeprazole, rabeprazole, lansoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-ATPase. PPIs reduce gastric acid secretion by up to 90% and are the drugs of choice for all but mild cases. Most patients with GORD will respond well, but this is only 20–30% of patients presenting with heartburn. Patients with severe symptoms may need twice-daily PPIs and prolonged treatment, often for years. Once oesophageal sensitivity has normalized, a lower dose, e.g. omeprazole 10 mg, may be sufficient for maintenance. The patients who do not respond to a PPI are sometimes described as having non-erosive reflux disease (NERD) (Fig. 6.11), when the endoscopy is normal. These patients are usually female and often the symptoms are functional, although a small group have a hypersensitive oesophagus, giving discomfort with only slight changes in pH. Isomers of

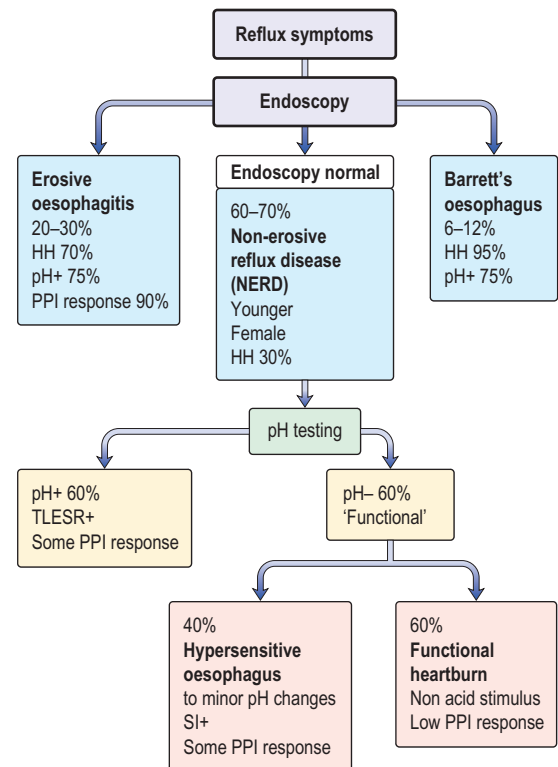

Figure 6.11 Outcome of patients with reflux symptoms. pH+, meets standard criteria for excessive acid reflux on intraluminal testing; pH–, does not meet standard criteria for excessive acid reflux; SI+, symptom index; TLESR, transient lower (o)esophageal sphincter relaxation; HH, hiatus hernia; PPI, proton pump inhibitor.

some of the original PPIs (e.g. dexlansoprazole) have the benefit of more effective gastric acid inhibition over a longer time period as their metabolism to the active metabolite is slower.

Endoluminal gastroplication

In this endoscopic procedure, multiple plications or pleats are made below the gastro-oesophageal junction. Randomized controlled trials have shown benefit with reduction in heartburn, acid reflux episodes and PPI usage.

Surgery

Surgery should never be performed for a hiatus hernia alone. The best predictors of a good surgical result are typical reflux symptoms with documented acid reflux, which correlates with symptoms and response to a PPI. With such highly selected cases in experienced hands, the laparoscopic Nissen fundoplication has over a 90% satisfaction rate at 5 years, and available 10-year data show satisfaction rates remain high at 88%. Current surgical techniques return the oesophagogastric junction to the abdominal cavity, mobilize the gastric fundus, close the diaphragmatic crura snugly and involve a short tension-free fundoplication.

Indications for operation are not clear cut but include intolerance to medication, the desire for freedom from medication, the expense of therapy and the concern of long-term side-effects. The most common cause of mechanical fundoplication failure is recurrent hiatus hernia.

Patients with oesophageal dysmotility unrelated to acid reflux, patients with no response to PPIs and those with underlying functional bowel disease should not have surgery.

Figure 6.12 The Prague Criteria for endoscopically suspected oesophageal columnar metaplasia/Barrett's oesophagus.

Complications

Peptic stricture

Since the advent of PPIs peptic strictures have become far less common. They usually occur in patients over the age of 60 and present with intermittent dysphagia for solids which worsens gradually over a long period. Mild cases may respond to PPI alone. More severe cases need endoscopic dilatation and long-term PPI therapy. Surgery is required if medical treatment fails.

Barrett's oesophagus

Barrett's oesophagus is a condition in which part of the normal oesophageal squamous epithelium is replaced by metaplastic columnar mucosa to form a segment of 'columnar-lined oesophagus' (CLO). It is a complication of gastro-oesophageal reflux disease and there is almost always a hiatus hernia present.

Diagnosis and classification. The diagnosis is made by endoscopy showing proximal displacement of the squamo-columnar mucosal junction and biopsies demonstrating columnar lining above the proximal gastric folds; intestinal metaplasia is no longer a requirement of the British Society of Gastroenterology definition, but is central to the American College of Gastroenterology guidelines. Barrett's oesophagus may be seen as a continual circumferential sheet, or finger-like projections extending upwards from the squamo-columnar junction or as islands of columnar mucosa

interspersed in areas of residual squamous mucosa. The Prague Classification (Fig. 6.12) is used for recording the endoscopic distribution, stating both the length of circumferential CLO (C measurement) as well as the maximum length (M measurement), the distance from the top of the gastric folds to the most proximal tongue of the columnar mucosa.

Central obesity increases the risk of Barrett's by 4.3 times. Long segment (>3 cm) and short segment (<3 cm) Barrett's is found respectively in 5% and 15% of patients undergoing endoscopy for reflux symptoms. It is also often found incidentally in endoscoped patients without reflux symptoms. Barrett's is commonest in middle-aged obese men. The major concern is that approximately 0.12–0.5% of Barrett's patients develop oesophageal adenocarcinoma per year, the majority, probably, through a gradual transformation from intestinal metaplasia to low-grade then high-grade dysplasia, before invasive adenocarcinoma. Barrett's increases the chance of developing oesophageal adenocarcinoma 30- to 50-fold in early studies but a recent study showed the risk to be much lower.

In the absence of high quality trial evidence, 2-yearly gastroscopies are recommended by some, at which time biopsies from all four quadrants (every 1–2 cm) of the CLO are taken, as well as biopsies from macroscopically abnormal areas. High-grade dysplasia (HGD) is usually associated with endoscopically visible nodules or ulceration which are optimally visualized with a high definition endoscope.

Endoscopic screening and surveillance in Barrett's oesophagus. Because of the poor correlation between Barrett's oesophagus and symptoms screening 'at risk' populations has not been shown to reduce the risk of oesophageal adenocarcinoma and is not recommended. As yet, there is no good evidence base for endoscopic surveillance of patients with established Barrett's oesophagus; however, a randomized control trial is currently underway. The global consensus currently favours 2-yearly screening (in the absence of dysplastic change) with endoscopic technology improving the detection of premalignant lesions and enabling their removal with either endoscopic mucosal resection (EMR) or endoscopic submucosal dissection, therefore preventing surgical oesophagectomy. However, recent data, which have shown a reduction in the incidence of Barrett's oesophagus, have cast doubt on this approach.

If *low-grade dysplasia* is found on endoscopic surveillance, a repeat endoscopy with quadrant biopsies every 1 cm is usually performed within 6 months, while on high-dose proton pump inhibition. Long-term surveillance in this group is controversial.

If *high-grade dysplasia* is found, this is usually in the context of an endoscopically visible lesion which, if nodular, is removed by endoscopic mucosal resection for more accurate histological staging. If high-grade dysplasia is detected in the absence of any endoscopically visible lesion high-dose proton pump inhibition is started and repeat biopsies taken within 3 months. Endoscopic ultrasound is frequently used to more accurately stage this patient group to exclude cancer and associated significant lymphadenopathy.

Radiofrequency ablation (RFA) has superseded photodynamic therapy as the technique of choice for endoscopic treatment of dysplasia within Barrett's segments following removal of any nodular lesions, returning the oesophagus to squamous lining. The benefit of RFA in low-grade dysplasia is currently under evaluation.

Motility disorders

Achalasia

Achalasia is characterized by oesophageal aperistalsis and impaired relaxation of the lower oesophageal sphincter.

Clinical features

Achalasia incidence is 1:100 000 equally in males and females. It occurs at all ages but is rare in childhood. Patients usually have a long history of intermittent dysphagia, characteristically for both liquids and solids from the onset. Regurgitation of food from the dilated oesophagus occurs, particularly at night, and aspiration pneumonia is a complication. Spontaneous chest pain occurs, said to be due to oesophageal 'spasm'. Dysphagia may be mild and accepted by the patient as normal. The pain may be misdiagnosed as cardiac. Weight loss is usually not marked.

Pathogenesis

The aetiology is unknown. Autoimmune, neurodegenerative and viral aetiologies have been implicated. A similar clinical picture is seen in chronic Chagas' disease (American trypanosomiasis, p. 148) where there is damage to the neural plexus of the gut.

Histopathology shows inflammation of the myenteric plexus of the oesophagus with reduction of ganglion cell

Figure 6.13 Barium swallow showing achalasia with atonic body of the oesophagus and a narrowed distal end (arrow). Note food residue in dilated oesophagus.

numbers. Cholinergic innervation appears to be preserved. Reduction in nitric oxide synthase-containing neurones has been shown by immunohistochemical staining. Pharmacological studies in patients with achalasia support the selective loss of *inhibitory*, nitrergic neurones. The differential diagnosis of achalasia worldwide includes genetic syndromes, infectious diseases, neoplasms and chronic inflammatory conditions.

Investigations

- **Chest X-ray** shows a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is absent.
- **Barium swallow** shows lack of peristalsis and often synchronous contractions in the body of the oesophagus, sometimes with dilatation. The lower end shows a 'bird's beak' due to failure of the sphincter to relax (Fig. 6.13).
- **Oesophagoscopy** is performed to exclude a carcinoma at the lower end of the oesophagus, which can produce a similar X-ray appearance. When there is marked dilatation, a 24-hour liquid-only diet and a washout prior to endoscopy is useful to remove food debris. In true achalasia the endoscope passes through the lower oesophageal sphincter with little resistance.
- **CT scan** excludes distal oesophageal cancer.
- **Manometry** shows aperistalsis of the oesophagus and failure of relaxation of the lower oesophageal sphincter (Fig. 6.7).

Treatment

All current forms of treatment for achalasia are palliative. Drug therapy rarely produces satisfactory or durable relief; nifedipine (20 mg sublingually) or sildenafil can be tried initially.

Endoscopic and surgical therapies are equally effective. Endoscopic dilatation of the LOS using a hydrostatic balloon under X-ray control weakens the sphincter and is successful initially in 80% of cases. About 50% of patients require a second or third dilatation in the first 5 years. There is a low but significant risk of perforation. Intraspincteric injection of

botulinum toxin A produces satisfactory initial results but the effects wear off within months. Further injections can be given. It is safer and simpler than dilatation, so may be valuable in patients at risk of death if a perforation occurs. Neither pneumatic dilatation nor botulinum toxin works as well in younger patients.

Surgical division of the LOS, Heller's operation, usually performed laparoscopically is the surgical treatment of choice. This can now be performed endoscopically.

Reflux oesophagitis complicates all procedures and the aperistalsis of the oesophagus remains.

Complications

There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

Systemic sclerosis

The oesophagus is involved in almost all patients with this disease. Diminished peristalsis and oesophageal clearance, detected manometrically (Fig. 6.7) or by barium swallow, is due to replacement of the smooth muscle by fibrous tissue. LOS pressure is decreased, allowing reflux with consequent mucosal damage. Strictures may develop. Initially there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes more severely involved. Similar motility abnormalities may be found in other autoimmune rheumatic disorders, particularly if Raynaud's phenomenon is present. Treatment is as for reflux (see p. 240) and benign stricture.

Diffuse oesophageal spasm

This is a severe form of oesophageal dysmotility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without normal peristalsis (Fig. 6.7). On barium swallow the appearance may be that of a 'corkscrew' oesophagus. However, asymptomatic oesophageal 'dysmotility' is not infrequent, particularly in patients over the age of 60 years.

A variant of diffuse oesophageal spasm is the 'nutcracker' oesophagus, which is characterized by very high-amplitude peristalsis (pressures >200 mmHg) within the oesophagus. Chest pain is commoner than dysphagia.

Treatment

True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. PPIs may be successful if reflux is a factor. Antispasmodics, nitrates, calcium-channel blockers and more recently GABA receptor agonists (e.g. baclofen) are used. Occasionally, balloon dilatation or even longitudinal oesophageal myotomy is necessary.

Miscellaneous motility disorders

Abnormalities of motility that occasionally produce dysphagia are found in the elderly, in diabetes mellitus, myotonic dystrophy, oculopharyngeal muscular dystrophy and myasthenia gravis, as well as neurological disorders involving the brainstem.

Other oesophageal disorders

Oesophageal diverticulum

Diverticula occur:

- Immediately **above** the upper oesophageal sphincter (pharyngeal pouch – Zenker's diverticulum) (see p. 1054).

- Near the **middle** of the oesophagus (traction diverticulum due to inflammation, or associated with diffuse oesophageal spasm or mediastinal fibrosis)
- Just above the **lower** oesophageal sphincter (epiphrenic diverticulum – associated with achalasia).

Usually detected incidentally on a barium swallow performed for other reasons, these are often asymptomatic. Dysphagia and regurgitation can occur with a pharyngeal pouch (see p. 1054).

Rings and webs

An oesophageal web is a thin, membranous tissue flap covered with squamous epithelium. Most acquired webs are located anteriorly in the postcricoid region of the cervical oesophagus and are well seen on barium swallow. They may produce dysphagia. In the *Plummer–Vinson syndrome* (or *Paterson–Brown–Kelly syndrome*), a web is associated with chronic iron deficiency anaemia, glossitis and angular stomatitis. This rare syndrome affects mainly women and its aetiology is not understood. The web may be difficult to see at endoscopy and may be ruptured unintentionally by the passage of the endoscope. Dilatation of the web is rarely necessary. Iron is given for the iron deficiency.

Lower oesophageal rings

Lower oesophageal rings are of two types:

1. **Mucosal (Schatzki's ring, also called B ring)** located at the squamocolumnar mucosal junction; it is common, and is associated with characteristic history of intermittent bolus obstruction. Barium swallow with a distended oesophagus shows the abnormality which may be difficult to see at endoscopy.
2. **Muscular (A ring)** located proximal to the mucosal ring and uncommon. It is covered by squamous epithelium and may cause dysphagia.

Treatment for these rings is usually with reassurance and dietary advice, but dilatation is occasionally necessary. After a single dilatation, 68% of patients with Schatzki's rings are symptom free at 1 year, 35% remain symptom free after 2 years, but only 11% are symptom free at 3 years. Many also respond to oral PPI, either alone or with dilatation.

Benign oesophageal stricture

Peptic stricture secondary to reflux is the most common cause of benign strictures (for treatment, see p. 241). They also occur after the ingestion of corrosives, after radiotherapy, after sclerosis of varices, and following prolonged nasogastric intubation. Dysphagia is usually treated by endoscopic dilatation. Surgery is sometimes required.

Oesophageal infections

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed (e.g. on chemotherapy) and debilitated patients and patients with AIDS. Infection can occur with:

- *Candida*
- Herpes simplex
- Cytomegalovirus
- Tuberculosis.

It is occasionally difficult to distinguish between these disorders either on barium swallow or oesophagoscopy, as only widespread ulceration is seen. In candidiasis, the

characteristic white plaques are frequently found; oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed. TB causes deep ulceration with associated mediastinal lymphadenopathy.

Treatment

Most patients on large doses of immunosuppressive agents are treated prophylactically for candida with nystatin or amphotericin. Other antifungal or antiviral treatment is given appropriately (see Ch. 4, p. 86).

Mallory–Weiss syndrome

This is described in this chapter.

Eosinophilic oesophagitis

Eosinophils can be seen in the oesophageal mucosa (which is usually devoid of eosinophils microscopically) due to a variety of causes such as eosinophilic (or allergic) oesophagitis and GORD.

Eosinophilic oesophagitis is being increasingly recognized but its pathogenesis is unknown. There may be a personal or family history of allergic disorders such as food allergy.

Patients present with a long history of dysphagia, food impaction, 'heartburn' and oesophageal pain. Usually the patient is male, white, and with an average age at diagnosis of 35, but it also occurs in children.

Typical endoscopic abnormalities include mucosal furrowing, loss of vascular pattern due to a thickened mucosa, plaques of eosinophilic surface exudate and prominent circular folds, but the oesophagus may appear macroscopically normal. Reflux oesophagitis and Schatzki's rings may co-exist. Endoscopic forceps biopsies ($\times 6$) should be taken from upper, mid and lower oesophagus for histology with eosinophil counts.

The eosinophilic infiltration of the oesophagus due to *reflux disease* can be excluded by rebiopsy after a 6-week course of full-dose PPI, when the eosinophil count will have fallen to below 15 per high power field.

Treatment is topical, swallowing inhaled steroid preparations such as fluticasone, budesonide syrup, systemic steroids or elimination diets (more beneficial in children). Mepolizumab, a humanized monoclonal antibody against IL-5, has shown some benefit in small trials. Dilatation is sometimes necessary, with a risk of perforation of 2%.

Oesophageal perforation or rupture

Oesophageal perforation most commonly occurs at the time of endoscopic dilatation and, rarely, following insertion of a nasogastric tube, gastroscope or transoesophageal echoprobe. Patients with malignant, corrosive or post-radiotherapy strictures are more likely to suffer perforation than those with a benign peptic stricture.

Management usually involves placement of an expanding covered oesophageal stent (see p. 246), which usually seals the hole. A water-soluble contrast X-ray is performed after 2–3 days to check the perforation has sealed.

'Spontaneous' oesophageal rupture occurs with violent vomiting (Boerhaave's syndrome), producing severe chest pain and collapse in typical cases. Diagnosis can be difficult because classic symptoms are absent in about a third of cases and delays in presentation for medical care are common. It may follow alcohol ingestion. A chest X-ray

shows a hydropneumothorax. The diagnosis is made with a water-soluble contrast swallow or on CT. The mortality rate is approximately 35%, making it the most lethal perforation of the GI tract. The best outcomes are associated with early diagnosis and definitive surgical management within 12 hours of rupture. If intervention is delayed longer than 24 hours, the mortality rate (even after surgery) rises to above 50% and to nearly 90% after 48 hours.

Oesophageal tumours

Cancer of the oesophagus

This is the sixth most common cancer worldwide. Squamous cancers occurring in the middle third account for 40% of tumours, and in the upper third, 15%. Adenocarcinomas occur in the lower third of the oesophagus and at the cardia and represent approximately 45% of tumours. Primary small cell cancer is extremely rare.

Epidemiology and aetiological factors

Squamous cell carcinoma (SCC)

The geographic variation in incidence is greater than for any other carcinoma – often in regions very close to one another. It is common in Ethiopia, China, South and east Africa and in the Caspian regions of Iran. By contrast, north, middle and west Africa have low rates.

In the UK, the incidence is 5–10 per 100000 and represents 2.2% of all malignant disease. The incidence of SCC is decreasing, in contrast to adenocarcinoma. SCC of the oesophagus is more common in men (2:1). Risk factors are shown in Table 6.5.

High levels of alcohol consumption increase the risk of squamous cell cancer of the oesophagus, while tobacco use is associated with an increased incidence of both squamous cell and adenocarcinomas of the oesophagus. Smoking, obesity and low fruit and vegetable consumption are implicated in approximately 9 in 10 squamous cell cancers of the oesophagus.

Diets rich in fibre, carotenoids, folate, vitamin C and non-starchy vegetables probably decrease the risk of oesophageal cancer whereas diets high in saturated fat and cholesterol and refined cereals have been associated with an increased risk. Red and processed meat intake has been associated with an increased risk of both oesophageal SCC and adenocarcinoma. Conversely, fish and white meat consumption have been inversely associated with risk of oesophageal SCC in case-control studies from Italy, Switzerland and Uruguay.

Table 6.5 Risk factors for cancer of the oesophagus

Squamous cell carcinoma	Adenocarcinoma
Tobacco smoking	Longstanding, heartburn
High alcohol intake	Barrett's oesophagus
Plummer–Vinson syndrome	Tobacco smoking
Achalasia	Obesity
Corrosive strictures	Breast cancer treated with radiotherapy
Coeliac disease	Older age
Breast cancer treated with radiotherapy	
Tylosis ^a	

^aTylosis is a rare autosomal dominant condition with hyperkeratosis of the palms and soles.

Figure 6.14 Carcinoma of the oesophagus. (a) Endoscopic image. (b) Barium swallow, showing an irregular narrowed area (arrows) at the lower end of the oesophagus. (c) Endoscopic ultrasound. The central concentric circles are the probe. The arrow points to a break in the muscle layer and the soft tissue mass of the carcinoma.

Adenocarcinoma

These tumours primarily arise in columnar-lined epithelium in the lower oesophagus (see also Barrett's oesophagus, p. 241). The incidence of this tumour is increasing in western industrialized countries). A study of the cancer registry in the USA estimated that incidence in white males rose four-fold from 1979 to 2004. Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms. Previous reflux symptoms increase the risk up to eight-fold and the risk is proportional to their severity.

Clinical features

Carcinoma of the oesophagus occurs mainly in those aged 60–70 years. Dysphagia is progressive and unrelenting. Initially, there is difficulty in swallowing solids, but typically dysphagia for liquids follows within weeks. Impaction of food causes pain, but more persistent pain implies infiltration of adjacent structures.

The lesion may be ulcerative, proliferative or scirrhous, extending variably around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures and metastases to lymph nodes are commoner than disseminated metastases. Weight loss, due to the dysphagia as well as to anorexia, is frequent. Oesophageal obstruction eventually causes difficulty in swallowing saliva, and coughing and aspiration into the lungs is common.

Weight loss, anorexia and lymphadenopathy are the commonest physical signs.

Investigation

Diagnostic

- **Endoscopy** provides histological and or cytological proof of the carcinoma (Fig. 6.14a).
- **Barium swallow** can be useful where the differential diagnosis of dysphagia includes a motility disorder such as achalasia (Fig. 6.14b).

Staging

The TNM staging system is used (see p. 253), similar to the one used for gastric cancer. Tumour invasion of the wall of the oesophagus (T), presence of tumour in lymph nodes (N) or metastases (M) are combined into stage categories. Tumours arising in the cervical, thoracic and oesophagus, or abdominal oesophagus, including those that arise from within 5 cm from the gastro-oesophageal junction, share the same TNM staging criteria, but recent reclassification has differentiated between squamous and oesophageal cancers.

- **CT scan** of the thorax and upper abdomen shows the volume of the tumour, local invasion, peritumoral and coeliac lymph node involvement and metastases in the lung and elsewhere.
- **MRI** is equivalent to CT in local staging but not as good for pulmonary metastases.
- **Endoscopic ultrasound** has an accuracy rate of nearly 90% for assessing depth of tumour and infiltration and 80% for staging lymph node involvement. It is useful if

CT does not show a lesion already too advanced for surgery. A fine-needle aspiration (FNA) of lymph nodes improves staging accuracy, particularly of the coeliac nodes. Accurate T staging is necessary as cancers confined to the superficial mucosa can be removed endoscopically (Fig. 6.14c).

- **Laparoscopy** is useful if the tumour is at the cardia, to look for peritoneal and node metastases.
- **Positron emission tomography (PET)** after fluorodeoxyglucose is used principally to confirm distant metastases suspected on CT.

Treatment

Although oesophageal SCC and adenocarcinomas are undoubtedly two different disease processes with independent tumour biology, the majority of trial data does not discriminate the two. Before 2010, they shared identical TNM staging system. How histology should influence treatment is therefore unclear and varies around the globe.

Treatment is dependent on the age and performance status of the patient and the stage of the disease. Five-year survival with stage 1 is 80% (T_1/T_2 , N_0 , M_0), stage 2 is 30%, stage 3 is 18% and stage 4 is 4%. Some 70% of patients present with stage 3 or greater disease, so that overall survival is 27% at 1 year and around 10% at 5 years. Management should be undertaken by multidisciplinary teams.

- **Surgery** provides the best chance of a cure but should only be used only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall. Less than 40% of patients will have potentially resectable disease at the time of presentation. Patients must be carefully evaluated preoperatively, particularly with regard to performance status (see p. 253), and surgery undertaken in designated units. Poor outcome data from surgery alone has challenged its role as monotherapy and it is more often used in conjunction with neo-adjuvant (preoperative) and adjuvant (postoperative) treatment.
- **Chemoradiation.** Preoperative ('neo-adjuvant') chemoradiation therapy may benefit patients with stage 2b and 3 disease. Prolongation of survival has been shown in some studies. In the USA neo-adjuvant chemoradiotherapy is preferred to the neo-adjuvant chemotherapy that is typically used in the UK.
- **Palliative therapy** is often the only realistic possibility. Dilatation is only of short-term benefit and the perforation risk is higher than for benign strictures. Combination of endoscopic dilatation with laser or brachytherapy (see p. 447) prolongs luminal patency and gives as good if not better functional results than stenting. Insertion of an expanding metal stent allows liquids and soft foods to be eaten.
- **Photodynamic therapy (PDT)** can be useful in more superficial cancers.
- **Chemoradiation** alone is sometimes given, but evidence of benefit is poor except in early stage SCC.
- **Nutritional support**, as well as support for the patient and their family, is vital in this distressing condition.

Other oesophageal tumours

Most other tumours are rare. Gastrointestinal stromal tumours (see p. 253) and leiomyomas (both submucosal tumours) are

found usually by chance; 10% cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions or those over 3 cm, which are more likely to harbour malignancy. Small benign tumours are relatively common and often do not require treatment.

Kaposi's sarcoma is found in the oesophagus as well as the mouth (see p. 193) and hypopharynx in patients with AIDS.

THE STOMACH AND DUODENUM

Structure

The stomach occupies a small area immediately distal to the oesophagus (the cardia), the upper region (the fundus, under the left diaphragm), the mid-region or body and the antrum, which extends to the pylorus (Fig. 6.8). It serves as a reservoir where food can be retained and broken up before being actively expelled in to the proximal small intestine.

The smooth muscle of the wall of the stomach has three layers: outer longitudinal, inner circular and innermost oblique layers. There are two sphincters, the gastro-oesophageal sphincter and the pyloric sphincter. The latter is largely made up of a thickening of the circular muscle layer and controls the exit of gastric contents into the duodenum.

The duodenum has outer longitudinal and inner smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates at the duodenojejunal flexure where it joins the jejunum.

- The **mucosal lining** of the stomach can stretch in size with feeding. The greater curvature of the undistended stomach has thick folds or rugae. The mucosa of the upper two-thirds of the stomach contains *parietal cells* that secrete hydrochloric acid, and *chief cells* that secrete pepsinogen (which initiates proteolysis). There is often a colour change at the junction between the body and the antrum of the stomach that can be seen macroscopically, and confirmed by measuring surface pH.
- The **antral mucosa** secretes bicarbonate and contains mucus-secreting cells and *G cells*, which secrete gastrin, stimulating acid production. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Somatostatin, a suppressant of acid secretion, is also produced by specialized antral cells (*D cells*).
- **Mucus-secreting cells** are present throughout the stomach and secrete mucus and bicarbonate. The mucus is made of glycoproteins called mucins.
- The **'mucosal barrier'**, made up of the plasma membranes of mucosal cells and the mucus layer, protects the gastric epithelium from damage by acid and, for example, alcohol, aspirin, NSAIDs and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see Fig. 15.30).
- The **duodenal mucosa** has villi like the rest of the small bowel, and also contains Brunner's glands that secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

Physiology

Acid secretion is central to the functionality of the stomach; factors controlling *acid secretion* are shown in Figure 6.15. Acid is not essential for digestion but does prevent some food-borne infections. It is under neural and hormonal control and both stimulate acid secretion through the direct action of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells.

a Control of acid secretion

b Mechanisms involved in acid secretion

Figure 6.15 (a) Control of acid secretion. (b) Mechanisms involved in acid secretion: Histamine stimulates G_s via the H_2 receptors and acts via cyclic AMP; prostaglandin E_2 activates the G_i protein and *inhibits* acid secretion; acetylcholine (ACh) acts via the vagus M_3 receptors; ACh also acts via the ECL cell; gastrin acts via the gastrin receptor, increasing the intracellular free calcium, and also via the ECL cell stimulating histamine. G_s and G_i , stimulating and inhibiting G-proteins; ECL, enterochromaffin cells.

Somatostatin inhibits both histamine and gastrin release and therefore acid secretion.

Other major gastric functions are:

- Reservoir for food
- Emulsification of fat and mixing of gastric contents
- Secretion of intrinsic factor
- Absorption (of only minimal importance).

Gastric emptying depends on many factors. There are osmoreceptors in the duodenal mucosa that control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

Gastritis and gastropathy

Gastritis

'Gastritis' indicates inflammation associated with mucosal injury (although the term is often used loosely by endoscopists to describe 'redness'), and 'gastropathy' indicates epithelial cell damage and regeneration without inflammation. Several classifications of gastritis (e.g. Sydney classification) have been proposed but are controversial due to lack of correlation, for example between endoscopic and histological findings. *H. pylori* infection is the commonest cause of gastritis (80%). Autoimmune gastritis is seen in 5%, while the remaining causes include viruses (e.g. cytomegalovirus and herpes simplex), duodenogastric reflux and specific causes, e.g. Crohn's, more common in children than adults.

Autoimmune gastritis

This affects the fundus and body of the stomach (pangastritis), leading to atrophic gastritis and loss of parietal cells with achlorhydria and intrinsic factor deficiency causing the clinical syndrome of 'pernicious anaemia'. Metaplasia, usually of the intestinal type, is almost always in the context of atrophic gastritis. Serum autoantibodies to gastric parietal cells are common and nonspecific: antibodies to intrinsic factor are rarer and more significant (see p. 382).

Gastropathy

Gastropathy is usually caused by irritants (drugs, NSAIDs and alcohol), bile reflux, hypovolaemia and chronic congestion. Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers) and secondary to burns (Curling ulcers), trauma, shock, renal failure or in portal hypertension (called portal gastropathy). The underlying mechanism for these ulcers is unknown but may be related to an alteration in mucosal blood flow.

Ménétrier's disease

This is a rare condition with characteristic giant gastric folds, mainly in the fundus and the body of the stomach. Histologically, there is hyperplasia of the gastric pits, atrophy of glands and an overall increase of mucosal thickness. Hyperchlorhydria is usually present. The patient may complain of epigastric pain. Peripheral oedema may occur because of hypoalbuminaemia due to protein loss through the gastric mucosa. It is probably premalignant but the rarity of the condition makes this uncertain. Treatment is unclear; some patients have responded to *Helicobacter* eradication and some improve spontaneously. Anti-secretory drugs are usually given. A few patients will require surgery.

Figure 6.16 *Helicobacter pylori*. (a) Organisms (arrowed) are shown on the gastric mucosa (cresyl fast violet (modified Giemsa) stain). (Courtesy of Dr Alan Phillips, Department of Paediatric Gastroenterology, Royal Free Hospital.) (b) Scanning electron microscopy, showing the spiral-shaped bacterium.

Helicobacter pylori infection

H. pylori is a slow-growing spiral Gram-negative flagellate urease-producing bacterium (Fig. 6.16) which plays a major role in gastritis and peptic ulcer disease. It colonizes the mucous layer in the gastric antrum, but is also found in the duodenum in areas of gastric metaplasia. *H. pylori* is found in greatest numbers under the mucous layer in gastric pits, where it adheres specifically to gastric epithelial cells. It is protected from gastric acid by the juxtamucosal mucous layer which traps bicarbonate secreted by antral cells, and ammonia produced by bacterial urease.

Epidemiology

The prevalence of *H. pylori* is high in developing countries (80–90% of the population), and much lower (20–50%) in developed countries. Infection rates are highest in lower income groups. Infection is usually acquired in childhood; although the exact route is uncertain, it may be faecal–oral or oral–oral. The incidence increases with age, probably due to acquisition in childhood when hygiene was poorer (cohort effect) rather than infection in adult life, which is probably far less than 1% per year in developed countries.

Pathogenesis

The pathogenetic mechanisms are not fully understood, with the majority of the colonized population remaining asymptomatic throughout their life. *H. pylori* is highly adapted to the stomach environment, exclusively colonizing gastric epithelium and inhabiting the mucous layer, or just beneath. It adheres by a number of adhesion molecules including BabA, which binds to the Lewis antigen expressed on the surface of gastric mucosal cells and causes gastritis in all infected subjects. Damage to the gastric epithelial cell is caused by the release of enzymes and the induction of apoptosis through binding to class II MHC molecules. The production of urease enables the conversion of urea to ammonium and chloride, which are directly cytotoxic. Ulcers are commonest when the infecting strain expresses CagA (cytotoxic-associated protein) and VacA (vacuolating toxin) genes secondary to a more pronounced inflammatory and immune response. Expression of CagA and VacA is associated with greater induction of IL-8, a potent mediator of gastric inflammation. Genetic variations in the host are also thought to be involved; for example, polymorphisms leading to increased levels of IL-1 β are associated with atrophic gastritis and cancer.

Results of infection

- Antral gastritis
- Peptic ulcers (duodenal and gastric)
- Gastric cancer.

Antral gastritis is the usual effect of *H. pylori* infection. It is usually asymptomatic, although patients without ulcers do sometimes experience relief of dyspeptic symptoms after *Helicobacter* eradication. Chronic antral gastritis causes hypergastrinaemia due to gastrin release from antral G cells. The subsequent increase in acid output is usually asymptomatic, but can lead to duodenal ulceration.

Duodenal ulcer (DU) (see Fig. 6.18a). The prevalence of *H. pylori* infection in patients with duodenal ulceration is falling and in the developed world is now between 50% and 75%, whereas duodenal ulceration was once rare in the absence of *H. pylori* infection. This has been attributed to a decrease in prevalence of the bacteria and an increase in NSAID use. Eradication of the infection improves ulcer healing and decreases the incidence of recurrence.

The precise mechanism of duodenal ulceration is unclear, as only 15% of patients infected with *H. pylori* (50–60% of the adult population worldwide) develop duodenal ulcers. Factors that have been implicated include: increased gastrin secretion, smoking, bacterial virulence and genetic susceptibility.

Gastric ulcer (GU) (see Fig. 6.18b). Gastric ulcers are associated with a gastritis affecting the body as well as the antrum of the stomach (pangastritis) causing parietal cell loss and reduced acid production. The ulcers are thought to occur because of reduction of gastric mucosal resistance due to cytokine production by the infection or perhaps to alterations in gastric mucus.

Peptic ulcer disease

A *peptic ulcer* consists of a break in the superficial epithelial cells penetrating down to the muscularis mucosa of either the stomach or the duodenum; there is a fibrous base and an increase in inflammatory cells. *Erosions*, by contrast, are superficial breaks in the mucosa alone. Most DUs are found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic or friable (duodenitis). GUs are most commonly seen on the lesser curve near the incisura, but can be found in any part of the stomach.

Epidemiology of peptic ulcer disease

Duodenal ulcers affect approximately 10% of the adult population and are two to three times more common than gastric ulcers.

Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly women. Both DUs and GUs are common in the elderly. There is considerable geographical variation, with peptic ulcer disease being more prevalent in developing countries related to the high *H. pylori* infection. In the developed world the percentage of NSAID-induced peptic ulcers is increasing, as the prevalence of *H. pylori* declines.

Clinical features of peptic ulcer disease

The characteristic feature of peptic ulcer is recurrent, burning epigastric pain. It has been shown that if a patient points with a single finger to the epigastrium as the site of the pain this is strongly suggestive of peptic ulcer disease. The relationship of the pain to food is variable and on the whole not helpful in diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry, but this is not reliable. The pain of both gastric and duodenal ulcers may be relieved by antacids.

Nausea may accompany the pain; vomiting is infrequent but can relieve the pain. Anorexia and weight loss may occur, particularly with GUs. Persistent and severe pain suggests complications such as penetration into other organs. Back

FURTHER READING

McColl KE. *Helicobacter pylori* infection. *N Engl J Med* 2010; 362:1597–1604.

Delaney B, Ford AC, Forman D et al. Initial management strategies for dyspepsia. *Cochrane Database Syst Rev* 2005; (4):CD001961.

pain suggests a penetrating posterior ulcer. Severe ulceration can occasionally be symptomless, as many who present with acute ulcer bleeding or perforation have no preceding ulcer symptoms.

Untreated, the symptoms of a DU relapse and remit spontaneously. The natural history is for the disease to remit over many years due to the onset of atrophic gastritis and a decrease in acid secretion.

Examination is usually unhelpful; epigastric tenderness is common in non-ulcer dyspepsia.

Diagnosis of *Helicobacter pylori* infection

Diagnosis of *H. pylori* is necessary if the clinician plans to treat a positive result. This is usually in the context of active peptic ulcer disease, previous peptic ulcer disease or MALT lymphoma, or to 'test and treat' patients with dyspepsia under the age of 55 with no alarm symptoms (i.e. weight loss, anaemia, dysphagia, vomiting, or family history of gastrointestinal cancer).

Non-invasive methods

- **Serological tests** detect IgG antibodies and are reasonably sensitive (90%) and specific (83%). They have been used in diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva, but tests are not as sensitive or specific as serology.
- **^{13}C -Urea breath test** (Fig. 6.17). This is a quick and reliable test for *H. pylori* and can be used as a screening test. The measurement of $^{13}\text{CO}_2$ in the breath after ingestion of ^{13}C urea requires a mass spectrometer. The test is sensitive (90%) and specific (96%), but the sensitivity can be improved by ensuring the patient has not taken antibiotics in the 4 weeks prior and proton pump inhibitors in the 2 weeks before the test.
- **Stool antigen test.** This is beginning to supersede breath testing as the method with which to determine *H. pylori* status. A specific immunoassay using monoclonal antibodies for the qualitative detection of *H. pylori* antigen is now widely available. The overall sensitivity is 97.6% with a specificity of 96%. It is useful

in the diagnosis of *H. pylori* infection and for monitoring efficacy of eradication therapy. Patients should be off PPIs for 2 weeks but can continue with H_2 blockers. Newer stool antigen tests are being developed that can be performed in the clinic setting, although at present the sensitivity and specificity are not as good as those performed in the laboratory.

Invasive (endoscopy)

- **Biopsy urease test.** Gastric biopsies, usually antral unless additional material is needed to exclude proximal migration, are added to a substrate containing urea and phenol red. If *H. pylori* are present, the urease enzyme that they produce splits the urea to release ammonia which raises the pH of the solution and causes a rapid colour change (yellow to red). This enables a patient's *H. pylori* status to be determined before they leave the endoscopy suite. The test may be falsely negative if patients are taking PPIs or antibiotics at the time.
- **Histology.** *H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy. The sensitivity is reduced if a patient is on PPIs, but less so than with the urease test. This can be improved with immunohistochemical staining using an anti *H. pylori* antibody.
- **Culture.** Biopsies obtained can be cultured on a special medium, and *in vitro* sensitivities to antibiotics can be tested. This technique is typically used for patients with refractory *H. pylori* infection to identify the appropriate antibiotic regimen and routine culture is rare.

Investigation of suspected peptic ulcer disease

- **Patients under 55 years of age** with typical symptoms of peptic ulcer disease who test positive for *H. pylori* can start eradication therapy without further investigation.
- Endoscopic diagnosis and exclusion of cancer is required in older patients (Fig. 6.18). All gastric ulcers must be biopsied to exclude an underlying malignancy and should be followed up endoscopically until healing has taken place.
- Endoscopy is required in all patients with 'alarm symptoms' (see p. 229).

Eradication therapy

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy if the bacteria is present. Many patients have incidental *H. pylori* infection with no gastric or duodenal ulcer. Whether all such patients should have eradication therapy is controversial (see Functional dyspepsia, p. 296).

The increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in the last few years is currently unexplained, but has been postulated to be linked

Figure 6.17 Metabolism of urea by *Helicobacter pylori* (Hp), showing the different tests that are available for the detection of *H. pylori*.

Figure 6.18 Endoscopic views. (a) Duodenal ulcer with inflamed duodenal folds. (b) Benign gastric ulcer.

to eradication of *H. pylori*. This seems unlikely but is not disproven.

Depending on local antibacterial resistance patterns standard eradication therapies in the developed world are successful in approximately 90% of patients.

Reinfection is very uncommon (1%) in developed countries. In developing countries reinfection is more common, compliance with treatment may be poor and metronidazole resistance is high (>50%) (as it is frequently used for parasitic infections), so failure of eradication is common.

There are many regimens for eradication, but all must take into account that:

- Good compliance is essential
- There is a high incidence of resistance to metronidazole and clarithromycin, particularly in some populations
- Oral metronidazole has frequent side-effects
- Bismuth chelate is unpleasant to take, even as tablets.

Metronidazole, clarithromycin, amoxicillin, tetracycline and bismuth are the most widely used agents. Resistance to amoxicillin (1–2%) and tetracycline (<1%) is low except in countries where they are available without prescription where resistance may exceed 50%. Quinolones such as ciprofloxacin, furazolidone and rifabutin are also used when standard regimens have failed ('rescue therapy'). None of these drugs is effective alone; eradication regimens therefore usually comprise two antibiotics given with powerful acid suppression in the form of a PPI. Recent evidence has advocated bismuth-containing quadruple therapy as first-line because of increasing clarithromycin resistance.

Example regimens are:

- Omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g all twice daily
- Omeprazole 20 mg + metronidazole 400 mg and clarithromycin 500 mg – all twice daily.

These should be given for 7 or 14 days. Two-week treatments increase the eradication rates but increased side-effects may reduce compliance. Bismuth chelate is not usually given in initial regimens because of the more complex dosing regimen and side-effects. However, a single capsule is now available.

In **eradication failures**, bismuth chelate (120 mg 4× daily); metronidazole (400 mg 3× daily); tetracycline (500 mg 4× daily) and a PPI (20–40 mg 2× daily) for 14 days, is used. Sequential courses of therapy are being used in areas where resistance is high. With the increase in clarithromycin resistance, many are using this quadruple therapy for initial treatment.

Prolonged therapy with a PPI after a course of PPI-based 7-day triple therapy is not necessary for ulcer healing in most *H. pylori*-infected patients. The effectiveness of treatment for uncomplicated duodenal ulcer should be assessed symptomatically. If symptoms persist, breath or stool testing should be performed to check eradication.

Patients with a risk of bleeding or those with complications, i.e. haemorrhage or perforation, should always have a ¹³C urea breath test or stool test for *H. pylori* 6 weeks after the end of treatment to be sure eradication is successful. Long-term PPIs may be necessary if a rebleed would be likely to be fatal.

General measures

Stopping smoking should be strongly encouraged, as smoking slows mucosal healing.

Box 6.4 Suspected perforated peptic ulcer

Look for:

- Other acute gastrointestinal conditions (e.g. cholecystitis, pancreatitis – check serum amylase)
- Non-GI conditions (e.g. myocardial infarction)
- Silent perforation in the elderly or patients on steroids

Remember:

- There is harm in leaving an undiagnosed perforation.

Patients with gastric ulcers should be routinely re-endoscoped at 6 weeks to exclude a malignant tumour by confirming healing with biopsy if necessary.

Complications of peptic ulcer

Haemorrhage

See page 256.

Perforation (Box 6.4; see also p. 299)

The frequency of perforation of peptic ulceration is decreasing, partly attributable to medical therapy. DUs perforate more commonly than GUs, usually into the peritoneal cavity; perforation into the lesser sac also occurs. Detailed management of perforation is described on page 301. Laparoscopic surgery is usually performed to close the perforation and drain the abdomen. Conservative management using nasogastric suction, intravenous fluids and antibiotics is occasionally used in elderly and very sick patients.

Gastric outlet obstruction

The obstruction may be prepyloric, pyloric or duodenal. The obstruction occurs either because of an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring. However, obstruction due to peptic ulcer disease and gastric malignancy are now uncommon; Crohn's disease or external compression from a pancreatic carcinoma are more common causes. Adult hypertrophic pyloric stenosis is a very rare cause.

After gastric outlet obstruction the stomach becomes full of gastric juice and ingested fluid and food, giving rise to the main symptom of vomiting, usually without pain as the characteristic ulcer pain has abated owing to healing.

Vomiting is infrequent, projectile, large in volume, and the vomitus contains particles of previous meals. On examination of the abdomen there may be a succussion splash. The diagnosis is made by endoscopy but can be suspected by the nature of the vomiting; by contrast, psychogenic vomiting is frequent, small volume and usually noisy.

Severe or persistent vomiting causes loss of acid from the stomach and a metabolic alkalosis (see p. 666). Vomiting will often settle with intravenous fluid and electrolyte replacement, gastric drainage via a nasogastric tube and potent acid suppression therapy. Endoscopic dilatation of the pyloric region is useful, as is luminal stenting, and overall, 70% of patients can be managed without surgery.

Surgical treatment and its long-term consequences

Once the mainstay of treatment, surgery is now used in peptic ulcer disease only for complications including:

- Recurrent uncontrolled haemorrhage: the bleeding vessel is ligated
- Perforation, which is oversewn.

No other procedure, such as gastrectomy or vagotomy, is required.

FURTHER READING

Gisbert JP, Calvet X, O'Connor JP et al. The sequential therapy regimen for *Helicobacter pylori* eradication. *Expert Opin Pharmacother* 2010; 11:905–918.

Malfertheiner P, Bazzoli F, Delchier JC et al.; Pylora Study Group. *Helicobacter pylori* eradication with a capsule containing bismuth subcitrate potassium, metronidazole, and tetracycline given with omeprazole versus clarithromycin-based triple therapy: a randomised, open-label, non-inferiority, phase 3 trial. *Lancet* 2011; 377:905–913.

In the past, two types of operation were performed:

- **Partial gastrectomy**
- **Vagotomy.** Initially this was a truncal vagotomy and required a gastric drainage procedure such as pyloroplasty or gastro-jejunostomy. In later years, this was usually highly selective vagotomy or proximal gastric vagotomy, in which only the nerves supplying the parietal cells were transected, and therefore no drainage of the stomach was required.
Long-term complications of surgery which are still seen occasionally include:
 - **Recurrent ulcer.** If this occurs, check for *H. pylori*; rule out Zollinger–Ellison syndrome (see p. 370). Malignancy needs to be excluded in all cases.
 - **Dumping.** This term describes a number of upper abdominal symptoms (e.g. nausea and distension) associated with sweating, faintness and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to ‘dumping’ of food into the jejunum, causing rapid fluid shifts from plasma to dilute the high osmotic load with reduction of blood volume. The symptoms are usually mild and patients adapt to them. It is rare for it to be a long-term problem, and if so, the symptoms usually have a functional element. Hypoglycaemia can also occur.
 - **Diarrhoea** was chiefly seen after vagotomy. Recurrent severe episodes occurred in about 1% of patients. Antidiarrhoeals are the usual treatment.
 - **Nutritional complications:** in the long term almost any gastric surgery, but particularly gastrectomy, may be followed by:
 - Iron deficiency, due to poor absorption
 - Folate deficiency, usually due to poor intake
 - Vitamin B₁₂ deficiency, due to intrinsic factor deficiency
 - Weight loss, usually due to reduced intake.

Other *H. pylori*-associated diseases

- **Gastric adenocarcinoma.** The incidence of distal (but not proximal) gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of distal gastric carcinoma (see p. 252).
- **Gastric B cell lymphoma.** Over 70% of patients with gastric B cell lymphomas (mucosal-associated lymphoid tissue – MALT) have *H. pylori*. *H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (see pp. 467 and 468).

NSAIDs, *Helicobacter* and ulcers

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main forms: COX-1, the constitutive enzyme, and COX-2, inducible by cytokine stimulation in areas of inflammation. COX-2 specific inhibitors have less effect on the COX-1 enzyme in the gastric mucosa, but still produce gastric mucosal damage but less than with other conventional NSAIDs. Their use is limited by concern regarding cardiovascular side-effects.

Some 50% of patients taking regular NSAIDs will develop gastric mucosal damage and approximately 30% will have

ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1–2% have a major problem, i.e. GI bleed. Because of the large number of patients on NSAIDs including low-dose aspirin for vascular prophylaxis, this is a significant problem, particularly in the elderly.

H. pylori and NSAIDs are independent and synergistic risk factors for the development of ulcers. In a meta-analysis, the odds ratio (OR) for the incidence of peptic ulcer was 61.1 in patients infected with *H. pylori* and also taking NSAIDs, compared with uninfected controls not taking NSAIDs.

Treatment

- Stop the ingestion of NSAIDs.
- A PPI should be given.
- *H. pylori* eradication therapy if *H. pylori* positive.
In many people with severe arthritis, stopping NSAIDs may not be possible. Therefore use:
 - An NSAID with low GI side-effects at lowest dose possible (see p. 511) or if there is no cardiovascular risk, a COX-2 NSAID can be used (see p. 511).
 - **Prophylactic cytoprotective therapy**, e.g. PPI or misoprostol (a synthetic analogue of prostaglandin E1 800 µg/day) for all high-risk patients, i.e. over 65 years; those with a peptic ulcer history, particularly with complications, and patients on therapy with corticosteroids or anticoagulants. PPIs reduce the risk of endoscopic duodenal and gastric ulcers and are better tolerated than misoprostol, which causes diarrhoea.

Gastric tumours

Adenocarcinoma

Gastric cancer is currently the fourth most common cancer found worldwide and the second leading cause of cancer-related mortality. The incidence increases with age (peak incidence 50–70 years), and it is rare under the age of 30 years. The highest incidences of the disease are found in Eastern Asia, Eastern Europe and South America. The incidence in men is twice that in women and varies throughout the world, being high in Japan (M: 53/100 000, F: 21.3/100 000) and Chile and relatively low in the USA (M: 7/100 000, F: 2.9/100 000). In the UK carcinoma of the stomach (see Fig. 6.1) is the eighth most common cancer (M: 16/100 000, F 9/100 000). Although the overall worldwide incidence of gastric carcinoma is falling, even in Japan, probably due to reductions in incidence of *Helicobacter* and before this, improvements in food storage, proximal gastric cancers are increasing in the West and have very similar demographic and pathological features as Barrett’s associated oesophageal adenocarcinoma.

Epidemiology and pathogenesis

- There is a strong link between *H. pylori* infection and distal gastric cancer. *H. pylori* is recognized by the International Agency for Research in Cancer (IARC) as a Group 1 (definite) gastric carcinogen. *H. pylori* infection causes chronic gastritis which eventually leads to atrophic gastritis and premalignant intestinal metaplasia (Fig. 6.19). Much of the earlier epidemiological data (i.e. the increase of cancer in lower socioeconomic groups) can be explained by the intrafamilial spread of *H. pylori*. Epstein–Barr virus is detected in 2–16% of gastric cancers worldwide, but its role in aetiology is not well understood.

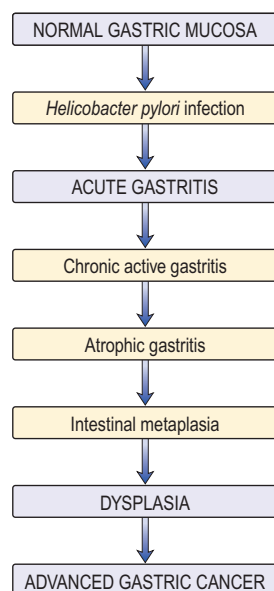

Figure 6.19 Flow diagram showing the development of gastric cancer associated with *H. pylori* infection.

- **Dietary factors** may also be involved (as both initiators and promoters) and have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted into nitrosamines by bacteria at neutral pH, and nitrosamines are known to be carcinogenic in animals but the evidence in human carcinogenesis is limited. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk.
- **Smoking tobacco** is associated with an increased incidence of stomach cancer.
- **Genetic abnormality.** The commonest is a loss of heterozygosity (LOH) of tumour suppressor genes such as p53 (in 50% of cancers as well as in pre-cancerous states) and the APC gene (in over one-third of gastric cancers). These abnormalities are similar to those found in colorectal cancers. Some rare families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene (CDH-1). There is a higher incidence of gastric cancer in blood group A patients.
- **First-degree relatives** of patients with gastric cancer have two- to three-fold increased relative risk of developing the disease, but this may be environmental rather than inherited.
- **Pernicious anaemia** carries a small increased risk of gastric carcinoma due to the accompanying atrophic gastritis.
- There is an increased risk of gastric cancer after a partial gastrectomy (postoperative stomach) whether performed for a gastric or a duodenal ulcer, probably due to untreated *H. pylori* infection.

Screening

Earlier diagnosis has been advocated in an attempt to improve the poor prognosis of gastric cancer. (Screening is discussed on p. 435.) Although the incidence of gastric cancer is falling in Japan where aggressive screening by barium meal and endoscopy is pursued, there is no evidence that screening has had an effect on overall mortality. Similarly, early investigation of dyspepsia has had little effect on

mortality, possibly because of the relatively low incidence of cancer.

Early gastric cancer

Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa, regardless of the presence of lymph node metastases. It is associated with 5-year survival rates of approximately 90%, but many of these patients would have survived 5 years without treatment. In Japan, mass screening with mobile X-ray units has increased the proportion of early gastric cancers (EGC) diagnosed. In a large series of patients with gastric cancer from the UK, only 0.7% were identified as having EGC. They are usually detected by chance as although EGC exists in western populations, endoscopists do not readily recognize it at present.

Pathology

There are two major types of gastric cancer:

- **Intestinal (type 1):** with well-formed glandular structures (differentiated). The tumours are polypoid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori*. This type is more likely to involve the distal stomach and occur in patients with atrophic gastritis. It has a strong environmental association.
- **Diffuse (type 2):** with poorly cohesive cells (undifferentiated) that tend to infiltrate the gastric wall, may involve any part of the stomach, especially the cardia, and have a worse prognosis than the intestinal type. Loss of expression of the cell adhesion molecule E-cadherin is the key event in the carcinogenesis of diffuse gastric cancers. Unlike type 1 gastric cancers, type 2 cancers have similar frequencies in all geographic areas and occur in a younger population.

Some 50% of gastric cancers in western countries occur in the proximal stomach.

Clinical features

Symptoms

Of patients with EGC discovered at screening, 50% have no symptoms. Most patients with carcinoma of the stomach have advanced disease at the time of presentation. The most common symptom of advanced disease is epigastric pain, indistinguishable from the pain of peptic ulcer disease; it may be relieved by food and antacids. The pain can vary in intensity, but may be constant and severe, and there may also be nausea, anorexia and weight loss. Vomiting is frequent and can be severe if the tumour encroaches on the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual, but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of early gastric cancer.

Widely spreading submucosal gastric cancer causes diffuse thickening and rigidity of the stomach wall and is called 'linitis plastica'.

Patients can present at a late stage with malignant ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Weight loss is often the dominant feature. Nearly 50% of patients have a palpable epigastric mass with abdominal

Figure 6.20 Carcinoma of the stomach. (a) Endoscopic picture showing a large irregular ulcer with rolled edges (arrow). (b) Axial CT scan (ulcer arrowed). (c) Histopathology showing an adenocarcinoma (arrows).

tenderness. A palpable lymph node is sometimes found in the supraclavicular fossa (Virchow's node, usually on the left side) and metastases are present in up to one-third of patients at presentation. This cancer is the most frequently associated with dermatomyositis (see p. 540) and acanthosis nigricans.

Diagnosis

- **Gastroscopy** (Fig. 6.20). Gastroscopy is performed so that biopsies can be taken for histological assessment. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8–10 biopsies should be taken from suspicious lesions. Superficial brushings for cytology further improve the diagnostic rate.

Staging

- **CT scan** of the chest and abdomen: CT with a gastric water load can demonstrate gastric wall thickening, lymphadenopathy and lung and liver secondaries, but has limited ability to determine the depth of local tumour invasion.
- **Transabdominal ultrasound** can demonstrate masses, gastric wall thickening, lymphadenopathy and liver secondaries.
- **Endoscopic ultrasound** is useful for local staging to demonstrate the depth of penetration of the cancer through the gastric wall and extension into local lymph nodes. It complements CT and ultrasound but is most relevant to confirm a cancer is confined to the superficial mucosa, before endoscopic resection.
- **Laparoscopy** is useful in patients being considered for surgery to exclude serosal disease.
- **PET and CT/PET** can be helpful in further delineation of the cancer.

The TNM classification is used. The tumour grade (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, M indicates presence or absence of metastases. TNM classification is then combined into stage categories 0–4. At presentation, two-thirds of patients are at stage 3 or 4, i.e. advanced disease (Table 6.6). The histological grade of the tumour also determines survival.

Treatment

As with all cancers, treatment is discussed with a multi-disciplinary team. Early non-ulcerated mucosal lesions can

Table 6.6 Gastric cancer – staging and 5-year survival rates

Stage	TNM stage	5-year survival (%)
1	T1N0M0, T1N1M0 or T2N0M0	88
2	T1N2M0, T2N1M0 or T3N0M0	65
3a	T2N2M0, T3N1M0 or T4N0M0	35
3b	T3N2M0	35
4	T4N1–3M0, TxN3M0 or TxNxM1 ^a	5

T, tumour; N, nodes; M, metastases. ^aTx indicates any T stage; Nx, any N stage.

be removed endoscopically by either endoscopic mucosal resection or endoscopic submucosal dissection.

Surgery remains the most effective form of treatment if the patient is an operative candidate. Careful selection has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates to around 30%. Five-year survival rates in 'curative' operations are as high as 50%. Surgery and combined chemoradiotherapy and treatment of advanced disease is described on page 477. The multinational MAGIC trial demonstrated the benefits of perioperative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) (see Table 9.10), where 5-year survival in operable gastric and lower oesophageal adenocarcinomas increased from 23% to 36%. An alternative regimen is oral epirubicin, oxaliplatin and capecitabine. Despite the improved results, the overall survival rate for a patient with gastric carcinoma has not dramatically improved, with a maximum 10% 5-year survival rate overall. Palliative care with relief of pain and counselling are usually required.

Gastrointestinal stromal tumours (GIST)

GI stromal tumours (GISTs) are a subset of GI mesenchymal tumours of varying differentiation. They are usually asymptomatic and found by chance but they can occasionally ulcerate and bleed. There are 200–900 new cases each year in the UK. GISTs mostly affect people between 55 and 65.

These tumours used to be classified as GI leiomyomas, leiomyosarcomas, leiomyoblastomas or Schwannomas. Truly benign leiomyomas do occur, mainly in the oesophagus. GISTs are now recognized as a distinct group of mesenchymal tumours and comprise about 80% of GI

FURTHER READING

Cunningham D, Allum WH et al. MAGIC trial: perioperative chemotherapy versus surgery alone for resectable gastroesophageal cancer. *N Engl J Med* 2006; 355:11–20.

mesenchymal tumours. They are of stromal origin, thought to share a common ancestry with the interstitial cells of Cajal. They have varying differentiation. Mutations occur in the cellular proto-oncogene KIT (which leads to activation and cell-surface expression of the tyrosine kinase KIT (CD 117)) in 80% and also in platelet-derived growth factor receptor- α (PDGFRA) in up to 10% of patients.

Treatment is surgical as far as possible. These tumours generally grow slowly but may be malignant. Imatinib, a tyrosine kinase inhibitor (p. 446), is used for unresectable or metastatic disease, and more recently as adjunctive therapy after surgical removal of the primary in the absence of metastatic disease. Some patients are resistant to this: sunitinib can be used as an alternative agent within a narrow time period.

Primary gastric lymphoma

Mucosa-associated lymphatic tissue lymphomas are indolent B cell marginal zone lymphomas primarily involving sites other than lymph nodes (gastrointestinal tract, thyroid, breast or skin). They constitute about 10% of all types of non-Hodgkin's lymphoma (NHL).

Presentation

Most patients are diagnosed in their 60s with stage I or stage II disease outside the lymph nodes. Patients have stomach pain, ulcers or other localized symptoms, but rarely have systemic complaints such as fatigue or fever.

Causes

About 90% of cases are due to *H. pylori* infection. Chromosome abnormalities t(1;14)(p22; q32) and t(11;18)(q21; q21) have also been noted in this form of NHL.

Treatment

Eradication of *H. pylori* infection may resolve cases of local gastric involvement. After standard eradication regimens, 50% of patients show resolution at 3 months. Other patients may resolve after 12–18 months of observation. Stage III or IV disease is treated with surgery or CHOP chemotherapy with or without radiation. The prognosis is good, with an estimated 90% 5-year survival.

Gastric polyps

Gastric polyps are found in about 1% of endoscopies, usually by chance. They rarely produce symptoms.

Endoscopic biopsy is the usual approach to diagnosis with possible polypectomy based on histological finding for treatment. Occasional large or multiple polyps may require surgery.

Hyperplastic polyps are by far the most common. Most are <2 cm. The polyps are rarely premalignant, but may be accompanied by premalignant atrophic gastritis.

Adenomatous polyps are usually solitary lesions in the antrum. Approximately 3% progress to gastric cancer, especially if >2 cm in diameter, but they are not a common cause of gastric cancer (*cf.* colorectal cancer).

Cystic gland polyps contain microcysts that are lined by fundic-type parietal and chief cells. They are located in the fundus and body of the stomach. They are found in otherwise normal subjects, but are especially common in familial polyposis syndromes and have no malignant potential, although low-grade dysplasia is seen in the absence of FAP and high grade exclusively in its presence.

Inflammatory fibroid polyps are benign spindle cell tumours infiltrated by eosinophils. Excision of these polyps

is indicated because of their propensity to enlarge and cause obstruction.

ACUTE AND CHRONIC GASTROINTESTINAL BLEEDING

This section should be read in conjunction with the descriptions of the specific conditions mentioned.

Acute upper gastrointestinal bleeding

The cardinal features are haematemesis (the vomiting of blood) and melaena (the passage of black tarry stools; the black colour due to blood altered by passage through the gut). Melaena can occur with bleeding from any lesion proximal to the right colon. Following a bleed from the upper GI tract, unaltered blood can appear per rectum, but the bleeding must be massive and is almost always accompanied by shock. The passage of dark blood and clots without shock is always due to lower GI bleeding.

Aetiology (Fig. 6.21)

Peptic ulceration is the commonest cause of serious and life-threatening gastrointestinal bleeding. The relative incidence of causes depends on the patient population; overall the incidence has fallen. In the developing world haemorrhagic viral infections (see Table 4.20) can cause significant gastrointestinal bleeding.

Drugs. Aspirin (even 75 mg/day) and other NSAIDs can produce ulcers and erosions. These agents are also responsible for GI haemorrhage from both duodenal and gastric ulcers, particularly in the elderly. They are available over the counter in the UK and patients may not be aware they are taking aspirin or an NSAID. Corticosteroids in the usual therapeutic doses have no influence on GI haemorrhage. Anti-coagulants do not cause acute GI haemorrhage *per se*

Figure 6.21 Causes of upper gastrointestinal haemorrhage. The approximate frequency is also given.

Table 6.7 Risk assessment in non-variceal upper gastrointestinal haemorrhage

Rockall risk assessment score				
Variable	Score			
	0	1	2	3
Age (years)	<60	60–79	>79	–
Circulation	BP >100 mmHg Pulse <100 b.p.m.	BP >100 mmHg Pulse >100 b.p.m.	BP <100 mmHg Pulse >100 b.p.m.	–
Co-morbidity	None		Cardiac disease, any other major co-morbidity	Chronic kidney disease, liver failure, disseminated malignancy
Endoscopic diagnosis	Mallory–Weiss tear, no lesion	All other diagnoses	Malignancy of the upper GI tract	–
Major SRH	None, or dark spots	–	Blood in the upper GI tract, adherent clot or spurting vessel	–

8+	42		41	

BP, blood pressure (systolic); SRH, stigmata of recent haemorrhage.

but bleeding from any cause is greater if the patient is anticoagulated.

Clinical approach to the patient

All cases with a recent (i.e. within 48 hours) significant GI bleed should be seen in hospital. In many, no immediate treatment is required as there has been only a small amount of blood loss. Approximately 85% of patients stop bleeding spontaneously within 48 hours.

Scoring systems have been developed to assess the risk of rebleeding or death.

Table 6.7 shows the Rockall score, which is based on clinical and endoscopy findings. The Blatchford score uses the level of plasma urea, haemoglobin and clinical markers but not endoscopic findings to determine the need for intervention such as blood transfusion or endoscopy in GI bleeding.

The following factors affect the risk of rebleeding and death:

- Age
- Evidence of co-morbidity, e.g. cardiac failure, ischaemic heart disease, chronic kidney disease and malignant disease
- Presence of the classical clinical features of shock (pallor, cold peripheries, tachycardia and low blood pressure)
- Endoscopic diagnosis, e.g. Mallory–Weiss tear, peptic ulceration
- Endoscopic stigmata of recent bleeding, e.g. adherent blood clot, spurting vessel
- Clinical signs of chronic liver disease.

Bleeding associated with liver disease is often severe and recurrent if it is from varices. Liver failure can develop.

Emergency Box 6.1

Management of acute gastrointestinal bleeding

- History and examination. Note co-morbidity
- Monitor the pulse and blood pressure half-hourly
- Take blood for haemoglobin, urea, electrolytes, liver biochemistry, coagulation screen, group and cross-matching (2 units initially)
- Establish intravenous access – 2 large bore i.v. cannulae
- Give blood transfusion/colloid if necessary. Indications for blood transfusion are:
 - a. SHOCK (pallor, cold nose, systolic BP below 100 mmHg, pulse >100 b.p.m.)
 - b. Haemoglobin <100 g/L in patients with recent or active bleeding
- Oxygen therapy
- Urgent endoscopy in shocked patients/liver disease
- Continue to monitor pulse and BP
- Re-endoscopy for continued bleeding/hypovolaemia
- Surgery if bleeding persists

Immediate management

This is shown in Emergency Box 6.1. In addition, stop NSAIDs, aspirin, clopidogrel and warfarin if patients are taking them. Stopping antiplatelets can be dangerous and produce thrombosis: discuss urgently with a cardiologist.

Many hospitals have multidisciplinary specialist teams with agreed protocols and these should be followed carefully. Patients should be managed in high-dependency beds. Oxygen should be given by facemask and the patient should be kept nil by mouth until endoscopy has been performed.

Patients with large bleeds and clinical signs of shock require urgent resuscitation. Details of the management of shock are given in Figure 16.25.

Acute and chronic gastrointestinal bleeding

Endoscopic view of GAVE (gastric antral vascular ectasia). Argon plasma coagulation catheter at 6 o'clock.

Blood volume

The major principle is to rapidly restore the blood volume to normal. This can be best achieved by transfusion of red cell concentrates via one or more large-bore intravenous cannulae; plasma expanders or 0.9% saline are given until the blood becomes available (see p. 887).

Transfusion must be monitored to avoid overload leading to heart failure, particularly in the elderly. The pulse rate and venous pressure are the best guides to adequacy of transfusion. A central venous pressure line is inserted for patients with organ failure who require blood transfusion, and in those most at risk of developing heart failure.

Haemoglobin levels are generally a poor indicator of the need to transfuse because anaemia does not develop immediately as haemodilution has not taken place. However, if the Hb is <100 g/L and the patient has either bled recently or is actively bleeding, transfusion is usually necessary. In most patients, the bleeding stops, albeit temporarily, so that further assessment can be made.

Endoscopy

Endoscopy will usually make a diagnosis, risk stratify and enable therapy to be performed if needed. Endoscopy should be performed as soon as possible after the patient has been resuscitated. Patients with Rockall scores of 0 or 1 pre-endoscopy may be candidates for immediate (see over) discharge and outpatient endoscopy the following day, depending on local policy.

Endoscopy can detect the cause of the haemorrhage in 80% or more of cases. In patients with a peptic ulcer, if the stigmata of a recent bleed are seen (i.e. a spurting vessel, active oozing, fresh or organized blood clot or black spots) the patient is more likely to rebleed. Calculation of the post-endoscopy Rockall score gives an indication of the risk of rebleeding and death.

At first endoscopy:

- Varices should be treated, usually with banding. Stenting for varices is a recent innovation, not yet widely available – see page 333, for management of varices and is an alternative to a Sengstaken tube in the control of bleeding oesophageal varices.
- Bleeding ulcers and those with stigmata of recent bleeding should be treated with two or three haemostatic methods, usually injection with epinephrine (adrenaline) and thermal coagulation (with heater probe, bipolar probe, laser or argon plasma coagulation) or endoscopic clipping because dual and triple therapy is more effective than monotherapy in reducing rebleeding.
- Antral biopsies should be taken to look for *H. pylori*. A positive biopsy urease test is valid, but a negative test is not reliable. If the urease test is negative, gastric histology should always be performed.

Drug therapy

After diagnosis at endoscopy, intravenous omeprazole 80 mg followed by infusion 8 mg/h for 72 hours should be given to all patients with actively bleeding ulcers or ulcers with a visible vessel, as it reduces rebleeding rates and the need for surgery. The majority of the landmark studies in this field have taken place in Hong Kong. H₂-receptor antagonists are of no value.

Uncontrolled or repeat bleeding

Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Surgery is necessary if bleeding is

persistent and/or uncontrollable and should aim primarily to control the haemorrhage.

Discharge policy

The patient's age, diagnosis on endoscopy, co-morbidity and the presence or absence of shock and the availability of support in the community should be taken into consideration. In general, all patients who are haemodynamically stable and have no stigmata of recent haemorrhage on endoscopy (Rockall Score pre-endoscopy 0, post-endoscopy <1) can be discharged from hospital within 24 hours. All shocked patients and patients with co-morbidity need longer inpatient observation.

Specific conditions

Oesophageal varices. These are discussed on page 924.

Mallory–Weiss tear. This is a linear mucosal tear occurring at the oesophagogastric junction and produced by a sudden increase in intra-abdominal pressure. It often occurs after a bout of coughing or retching and is classically seen after alcoholic 'dry heaves'. There may, however, be no antecedent history of retching. Most bleeds are minor and discharge is usual within 24 hours. The haemorrhage may be large but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows therapy if necessary. Surgery with oversewing of the tear is rarely needed.

Chronic peptic ulcer. Eradication of *H. pylori* is started as soon as possible (see p. 249). A PPI is continued for 4 weeks to ensure ulcer healing. Eradication of *H. pylori* should always be checked in a patient who has bled and long-term acid suppression given if HP eradication is not achieved. If bleeding is not controlled the patient should either undergo angiography and embolization or be referred directly for surgery.

Gastric carcinoma. Most of these patients do not have large bleeds but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually, surgery can be delayed until the patient has been fully evaluated (see p. 253). Oozing from gastric cancer is very difficult to control endoscopically. Radiotherapy can occasionally be successful.

Bleeding after percutaneous coronary intervention (PCI). In the era of ever more aggressive percutaneous coronary intervention the list of anti thrombotic medication grows longer: glycoprotein IIb/IIIa inhibitors, unfractionated heparin, low molecular weight heparin, fondaparinux, platelet inhibitors (e.g. clopidogrel, prasugrel). These, in addition to the oral anticoagulants that this group of patients are often taking, give rise to a GI bleeding rate of approximately 2% of patients undergoing PCI (who are on antiplatelet therapy, e.g. clopidogrel), and has a high mortality of 5–10%. It has become increasingly evident in this patient group that gastroscopy should be performed on an urgent basis and not deferred for days or weeks. A bolus of i.v. PPI is administered followed by an infusion; platelet infusion is given to counter the effect of clopidogrel. Management is difficult as cessation of antiplatelet therapy has a high risk of acute stent thrombosis and also an associated high mortality. Using a risk assessment score (e.g. Rockall, Table 6.7), a reasonable approach is to stop all antiplatelet therapy in high-risk patients but continue in low-risk ones. Co-prescribed proton pump inhibition does not decrease the antiplatelet effect of clopidogrel as was first thought. These patients should be under the combined care of a cardiologist and a gastroenterologist.

Prognosis

The mortality from gastrointestinal haemorrhage has not changed from 5–12% over the years, despite many changes

Figure 6.22 Causes of lower gastrointestinal bleeding. The sites shown are illustrative – many of the lesions can be seen in other parts of the colon.

in management, mainly because of a demographic shift to more elderly patients with co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical GI units.

Acute lower gastrointestinal bleeding

Massive bleeding from the lower GI tract is rare and usually due to diverticular disease or ischaemic colitis. Common causes of small bleeds are haemorrhoids and anal fissures. The causes of lower GI bleeding are shown in Figure 6.22.

Management

Most acute lower GI bleeds start and stop spontaneously. The few patients who continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper GI bleeding (see p. 255). Surgery is rarely required.

A diagnosis is made using the history, examination including rectal examination and the following investigations as appropriate:

- Proctoscopy (e.g. anorectal disease, particularly haemorrhoids)
- Flexible sigmoidoscopy or colonoscopy (e.g. inflammatory bowel disease, cancer, ischaemic colitis, diverticular disease, angiodysplasia)
- Angiography – vascular abnormality (e.g. angiodysplasia). The yield of angiography is low, so it is a test of last resort.

Isolated episodes of rectal bleeding in the young (<45 years) usually only require rectal examination and flexible sigmoidoscopy because the probability of a significant proximal lesion is very low unless there is a strong family history of colorectal cancer at a young age. Individual lesions are treated as appropriate.

Chronic gastrointestinal bleeding

Patients with chronic bleeding usually present with iron-deficiency anaemia (see Ch. 8).

Chronic blood loss producing iron deficiency anaemia in all men, and all women after the menopause, is always due to bleeding from the GI tract. The primary concern is to exclude cancer, particularly of the stomach or right colon, and coeliac disease. Occult blood tests are unhelpful

Box 6.5 Measurement of faecal occult blood

This is frequently performed unnecessarily. It is only of value in:

- Premenopausal women – if a history of menorrhagia is uncertain and the cause of iron deficiency is unclear
- Mass population screening for large bowel malignancy

Advantages: cheap and easy to perform

Disadvantages: high false-positive rate, leading to unnecessary investigations

(Box 6.5). Iron deficiency anaemia can be due to poor iron intake (rare) or absorption as well as chronic blood loss.

Diagnosis

Chronic blood loss can occur with any lesion of the GI tract that produces acute bleeding (Figs 6.21, 6.22). However, oesophageal varices usually bleed obviously and rarely present as chronic blood loss. Although uncommon in developed countries, hookworm is the most common worldwide cause of chronic GI blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available it is usual to investigate both the upper and lower GI tract endoscopically at the same session ('top and tail'):

- **Upper gastrointestinal endoscopy** is usually performed first. Duodenal biopsies should always be taken to exclude coeliac disease, which is a recognized cause of iron deficiency.
- **Colonoscopy** follows and any lesion should be biopsied or removed, though it is not safe to assume that colonic polyps are the cause of chronic blood loss.
- **Unprepared CT** scanning is a reasonable test to look for colon cancer in frail patients.
- **CT colonography** can be used as an alternative to colonoscopy.

If gastroscopy, colonoscopy and duodenal biopsy have not revealed the cause, investigation of the small bowel is necessary. *Capsule endoscopy* is the diagnostic investigation of choice, but currently has no therapeutic ability. Positive diagnostic yield varies from 60% to 85% depending on series. Bleeding lesions can be identified and later treated with balloon-assisted enteroscopy.

Occasionally, intravenous technetium-labelled colloid may be used to demonstrate a potential bleeding site in a Meckel's diverticulum.

Treatment

The cause of the bleeding should be treated, if found. Oral iron is given to treat anaemia (see p. 380), although intravenous infusions are occasionally required. Some patients will require maintenance with regular transfusion as a last resort.

THE SMALL INTESTINE

Structure

The small intestine extends from the duodenum to the ileocaecal valve. It is approximately 3–6 m in length, and 300 m² in surface area. The upper 40% is the duodenum and jejunum, the remainder is the ileum. Its surface area is enormously increased by circumferential mucosal folds that have on them multiple finger-like projections called villi. On the villi the surface area is further increased by microvilli on the luminal side of the epithelial cells (enterocytes) (Fig. 6.23).

The small intestine

Angiodysplastic lesions (arrows) seen on video capsule endoscopy.

Figure 6.23 Structure of the small intestine.

Each villus consists of a core containing blood vessels, lacteals (lymphatics) and cells (e.g. plasma cells and lymphocytes). The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils and mast cells. The crypts of Lieberkühn are the spaces between the bases of the villi.

Enterocytes are formed at the bottom of the crypts and migrate toward the tops of the villi, where they are shed. This process takes 3–4 days. On its luminal side, the enterocyte is covered by microvilli and a gelatinous layer called the glycocalyx. Scattered between the epithelial cells are mucin-secreting goblet cells and occasional intraepithelial lymphocytes and Paneth cells. Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries – there are no local anastomotic connections.

Enteric nervous system (ENS)

This controls the functioning of the small bowel; it is an independent system that coordinates absorption, secretion, blood flow and motility. It is estimated to contain 10^8 neurones (as many as the spinal cord) contained in two major ganglionated plexuses: the myenteric plexus between the muscular layers of the intestinal wall, and the submucosal plexuses associated with the mucosa. The ENS communicates with the central nervous system via autonomic afferent and efferent pathways but can operate autonomously.

Coordination of small intestinal function involves a complex and poorly understood interplay between many neuroactive mediators and their receptors, ion channels, GI hormones, nitric oxide and other transmitters. Acetylcholine, adrenaline, ATP, vasoactive intestinal peptide (VIP) and other hormones and opioids have been shown to have actions in the small bowel, but the exact role for each is far from being understood.

Gut motility

The contractile patterns of the small intestinal muscular layers are primarily determined by the enteric nervous system. The CNS and gut hormones also have a modulatory

role on motility. The interstitial cells of Cajal which lie within the smooth muscle appear to govern rhythmic contractions.

During fasting, a distally migrating sequence of motor events termed the migrating motor complex (MMC) occurs in a cyclical fashion. The MMC consists of

- A period of motor quiescence (phase I),
- followed by a period of irregular contractile activity (phase II),
- culminating in a short (5–10 min) burst of regular phasic contractions (phase III).

Each MMC cycle lasts for approximately 90 min. In the duodenum, phase III is associated with increased gastric, pancreatic and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food and desquamated cells towards the colon. It is named the 'intestinal housekeeper'.

After a meal, the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic pattern lasts typically for 2–5 hours after feeding, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing function, moving intraluminal contents to and fro, aiding the digestive process.

Neuroendocrine peptide production

The hormone-producing cells of the gut are scattered diffusely throughout its length and also occur in the pancreas. The cells that synthesize hormones are derived from neural ectoderm and are known as APUD (amine precursor uptake and decarboxylation) cells. Many of these hormones have very similar structures and their action is probably local.

Gut hormones play a part in the regulation and integration of the functions of the small bowel and other metabolic activities. Their actions are complex and interacting, both with each other and with the ENS (Table 6.8).

Physiology

In the small bowel digestion and absorption of nutrients and ions takes place, as does the regulation of fluid absorption and secretion. The epithelial cells of the small bowel form a physical barrier that is selectively permeable to ions, small molecules and macromolecules. Digestive enzymes such as proteases and disaccharidases are produced by intestinal cells and expressed on the surface of microvilli; others such as lipases produced by the pancreas are associated with the glycocalyx. Some nutrients are absorbed most actively in specific parts of the small intestine; iron and folate in the duodenum and jejunum, vitamin B₁₂ and bile salts in the terminal ileum where they have specific receptors.

General principles of absorption

Simple diffusion

This process is nonspecific, requires no carrier molecule or energy and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the blood-stream (low concentration). Vitamin B₁₂ can be absorbed from the jejunum by this means.

Facilitated diffusion

Absorption takes place down a concentration gradient, but a membrane carrier protein is involved, conferring specificity on the process. Fructose is an example.

Table 6.8 Gut regulatory peptides

Peptide	Localization	Main actions
Gastrin/cholecystokinin family		
Cholecystokinin (CCK) Multiple forms from CCK8 (8 amino acids) to CCK83; 8, 33 and 58 are predominant. Terminal 5 amino acids same as gastrin	Duodenum and jejunum (I cells) Enteric nerves CNS	Causes gall bladder contraction and sphincter of Oddi relaxation. Trophic effects on duodenum and pancreas. Pancreatic secretion (minor role). Role in satiety – acting in CNS
Gastrin	G cells in gastric antrum and duodenum	Stimulates acid secretion. Trophic to mucosa
Secretin-glucagon family		
Secretin Glucagon Vasoactive polypeptide (VIP)	Duodenum and jejunum (S cells) Alpha cells of pancreas Enteric nerves	Stimulates pancreatic bicarbonate secretion Opposes insulin in blood glucose control Intestinal secretion of water and electrolytes. Neurotransmitter. Splanchnic vasodilatation, stimulates insulin release
Glucose-dependent insulintropic peptide (GIP)	Duodenum (K cells) Gastric antrum Ileum	Release by intraduodenal glucose causes greater insulin release by islets than i.v. glucose (incretin effect)
Glucagon-like peptide-1 (GLP-1)	Ileum and colon (L cells) Co-secreted with GLP1	Incretin. Stimulates insulin synthesis. Trophic to islet cells. Inhibits glucagon secretion and gastric emptying
Glicentin	L cells	Stimulates growth of enterocytes Stimulates insulin secretion and gut growth, inhibits gastric secretion
Growth hormone-releasing factor (GHRF)	Small intestine	Unclear
Pancreatic polypeptide family		
Pancreatic polypeptide (PP) Peptide YY (PYY)	Pancreas (PP cells) Ileum and colon (L cells)	Inhibits pancreatic and biliary secretion Inhibits pancreatic exocrine secretion. Slows gastric and small bowel transit ('ileal brake'). Reduces food intake and appetite
Neuropeptide Y (NPY)	Enteric nerves	Stimulates feeding. Regulates intestinal blood flow
Other		
Motilin	Whole gut	Increases gastric emptying and small bowel contraction
Ghrelin	Stomach	Stimulates appetite, increases gastric emptying
Obestatin	Stomach and small intestine	Opposes ghrelin
Oxyntomodulin	Colon	Inhibits appetite
Gastrin releasing-polypeptide (bombesin)	Whole gut and pancreas	Stimulates pancreatic exocrine secretion and gastric acid secretion
Somatostatin	Stomach and pancreas (D cells) Small and large intestine	Inhibits secretion and action of most hormones
Substance P	Enteric nerves	Enhances gastric acid secretion, smooth muscle contraction
Neurotensin	Ileum	Affects gut motility. Increases jejunal and ileal fluid secretion
Insulin	Pancreatic β cells	Increases glucose utilization
Chromogranins	Neuroendocrine cells	Precursor for other regulatory peptides that inhibit neuroendocrine secretion

Active transport

Absorption occurs via a specific carrier protein, powered by cellular energy, and thus a substance can be transported against a concentration gradient. Many carrier proteins are powered by ion gradients across the enterocyte wall. For example, glucose crosses the enterocyte microvillous membrane from the lumen into the cell against a concentration gradient by using a *co-transporter* carrier molecule. This is the sodium/glucose co-transporter, SGLT1 (Fig. 6.24). The process is powered by the energy derived from the flow of Na^+ ions from a high concentration outside the cell to a low concentration inside. The sodium gradient across the cell wall is maintained by a separate ATP-consuming Na^+/K^+ exchanger in the basolateral membrane. Glucose leaves the cell on the serosal side by facilitated diffusion via a sodium-independent carrier (GLUT-2) in the basolateral membrane.

Another active transport mechanism operates for Na^+ absorption in the ileum using an Na^+/H^+ exchange

mechanism powered by the outwardly directed gradient of H^+ across the cell membrane.

Absorption of nutrients in the small intestine**Carbohydrate**

Dietary carbohydrate consists mainly of starch, with some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. In order to have a nutrient value starch must be digested into smaller oligo-, di- and finally monosaccharides which may then be absorbed. Polysaccharide hydrolysis begins in the mouth catalysed by salivary amylase, though the majority takes place under the action of pancreatic amylase in the upper intestine. The breakdown products of starch digestion are maltose and maltotriose, together with sucrose and lactose. These are further hydrolysed on the microvillous membrane by specific oligo- and disaccharidases to form glucose, galactose and fructose. These monosaccharides are then able to be transported across the enterocytes into the blood (Fig. 6.24).

Figure 6.24 Transcellular uptake of glucose across the intestinal epithelia. Glucose is co-transported across the apical membrane with sodium ions by the sodium-dependent glucose transporter (SGLT). This is secondary active transport as the sodium is travelling down its electrochemical gradient. The sodium gradient is maintained by the primary active transport of sodium across the basolateral membrane by the Na^+K^+ ATPase (thus intracellular Na^+ is kept low). Transcellular transport of glucose is achieved by facilitated diffusion across the basolateral membrane as glucose is moved down its concentration gradient by GLUT-2.

Protein

Dietary protein is digested by pancreatic proteolytic enzymes to amino acids and peptides prior to absorption. These enzymes are secreted by the pancreas as pro-enzymes and transformed to active forms in the lumen. Protein in the duodenal lumen stimulates the enzymatic conversion of trypsinogen to trypsin, and this in turn activates the other pro-enzymes, chymotrypsin and elastase.

These enzymes break down protein into oligopeptides. Some di- and tri-peptides are absorbed intact by carrier-mediated processes, while the remainder are broken down into free amino acids by peptidases on the microvillous membranes of the enterocytes, prior to absorption into the cell by a variety of amino acid and peptide carrier systems.

Fat

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Fat is emulsified by mechanical action in the stomach. Bile containing the amphipathic detergents, bile acids and phospholipids enters the duodenum following gall bladder contraction. They act to solubilize fat and promote hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides. Bile acids, phospholipids and the products of fat digestion cluster together with their hydrophilic ends on the outside to form aggregations called mixed micelles. Trapped in the centre of the micelles are the hydrophobic monoglycerides, fatty acids and cholesterol. At the cell membrane the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell the monoglycerides and

fatty acids are re-esterified to triglycerides. The triglycerides and other fat-soluble molecules (e.g. cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

By contrast, another mechanism exists for medium-chain triglycerides (MCT; fatty acids of chain length 6–12) which are transported via the portal vein with a small amount of long-chain fatty acid. Patients with pancreatic exocrine or bile salt insufficiency can therefore supplement their fat absorption with MCT.

Bile salts are not absorbed in the jejunum, so the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see p. 306).

The pathophysiology of fat absorption is shown in Figure 6.25. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (>17 mmol or 6 g of faecal fat per day).

Water and electrolytes

Large amounts of water and electrolytes, partly dietary, but mainly from intestinal secretions, are absorbed coupled with absorption of monosaccharides, amino acids and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly (between the enterocytes) down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and colon, where active sodium transport is not coupled to solute absorption. Secretion of fluid and electrolytes occur together to maintain the normal functioning of the gut. Secretory diarrhoea (see p. 292) can occur because of defects in intestinal secretory mechanisms.

Water-soluble vitamins, essential metals and trace elements

These are all absorbed in the small intestine. Vitamin B_{12} (see p. 382) and bile salts are absorbed by specific transport mechanisms in the terminal ileum; malabsorption of both these substances often occurs following ileal resection.

Calcium absorption

Calcium absorption is discussed on page 548.

Iron absorption

Iron absorption is discussed on page 377.

Response of the small bowel to antigens and pathogens

The small bowel has a number of mechanisms to prevent colonization and invasion by pathogens while simultaneously preventing inappropriate responses to foreign antigens or the indigenous bacterial population. At the same time commensal bacteria maintain the integrity of the small bowel and play a major role in host physiology.

Mechanisms

Physical defence

- The mucus layer
- Continuous shedding of surface epithelial cells
- The physical movement of the luminal contents
- Colonization resistance – the ability of the indigenous microbiota to outcompete pathogens for a survival niche in the gut.

a The pathophysiology of fat absorption

b The formation of mixed micelles

Figure 6.25 (a) The pathophysiology of fat absorption. (b) Diagram showing the formation of mixed micelles.

Innate chemical defence

- **Enzymes** such as lysozyme and phospholipase A_2 secreted by Paneth cells at the base of the crypts help ensure an infection-free environment in the gut, even in the presence of commensal bacteria.
- **Antimicrobial peptides** are secreted from enterocytes and Paneth cells in response to pathogenic bacteria. These include *defensins*, which are 15–20 amino acid peptides with potent activity against a broad range of pathogens including Gram-positive and Gram-negative bacteria, fungi and viruses.
- **Trefoil peptides** are a family of small proteins secreted by goblet cells. They consist of a three-loop structure with intra-chain disulphide bonds which makes the molecules highly resistant to digestion. Their actions include stabilization of mucus, promotion of cell migration over injured areas, and promotion of repair. Three trefoil factors (TFF) are found in humans (TFF1, TFF2 and TFF3) all of which have been implicated in the response to gastrointestinal injury in experimental models. Their molecular mode of action is not yet known.

Innate immunological defence

- **Humoral.** IgA is the principal mucosal antibody. IgA mediates mucosal immunity by agglutinating and neutralizing pathogens in the lumen and preventing colonization of the epithelial surface (Fig. 6.26). IgA is secreted from immunocytes in the lamina propria as dimers joined by a protein called the 'Joining chain' (J-chain); in this form it is known as polymeric IgA

(pIgA). This pIgA is internalized by endocytosis at the basolateral membrane of enterocytes. It crosses the cell as a complex of pIgA/pIgAR and is secreted onto the mucosal surface.

- **B-cell sensitization.** Antigens from the lumen of the bowel are transported by M cells and dendritic cells in the follicle-associated epithelium (FAE). This covers Peyer's patches in the 'dome' region which contain abundant virgin B cells, helper T cells and antigen-presenting cells. Activated B cells then produce IgA locally and are programmed to home back to the lamina propria. They travel through mesenteric lymph nodes and then via the thoracic duct to the blood and back to the small bowel and other mucosal surfaces (such as the airways) where they undergo terminal differentiation into plasma cells. Homing back to the gut is facilitated by the $\alpha 4\beta 7$ -integrin on gut-derived lymphocytes binding to MAdCAM-1, uniquely expressed on blood vessels in the gut.
- **Cellular defence.** T lymphocytes also provide host defence and initiate, activate and regulate adaptive immune responses. Intestinal T lymphocytes occur principally in three major compartments:
 1. Organized gut-associated lymphoid tissue (GALT) such as Peyer's patches where mucosal T cell responses are generated, and after which cells leave the organized lymphoid tissue and home back to the mucosa
 2. The lamina propria, containing mostly CD4 cells

Figure 6.26 Small intestinal mucosa with a Peyer's patch, showing the gut-associated lymphoid tissue (GALT).

Inset i: (1) Specialized 'M' cells within a lymphoid follicle pass antigen to underlying APC such as DC. (2) DC present antigen to T cells resulting in activation and effector responses.

Inset ii: (1) DC pass dendrites through epithelial tight junctions to sample luminal antigen. (2) DC traffic to the mesenteric lymph node and present antigen to naive T cells which differentiate into effector or regulatory subtypes and are imprinted with a gut homing integrin. (3) On subsequent antigen presentation, activated T cells home to lamina propria and exert regulatory or inflammatory effect depending on their phenotype. DC, dendritic cell.

3. The surface epithelium where these lymphocytes are known as intraepithelial lymphocytes (IELs) and are mostly CD8 cells. T cells are sensitized to antigen in the Peyer's patch lymphoid tissue in a similar fashion to B cells, pass through mesenteric lymph nodes into the thoracic duct and into the circulation, homing back to the small bowel to end up in the lamina propria or the epithelium. It is probable that IELs are cytotoxic cells, capable of killing virally or bacterially infected epithelial cells. CD4 cells in the lamina propria of healthy individuals are highly activated cells, probably protecting against low-grade infections, since loss of these cells, as in HIV infection, leads to colonization of the gut by protozoa such as cryptosporidia.

Commensal bacteria

The relationship between the hundred thousand billion microbes in the human gut and the host are only beginning to be appreciated. Germ-free mice have essentially no mucosal immune system showing that the abundant and activated immune system seen in healthy individuals is driven by the flora, without adverse effects. Bacteria also release chemical signals such as LPS and lipoteichoic acid

that are recognized by Toll-like receptors (TLRs) (see p. 55) present on a variety of intestinal cells, priming repair processes and enhancing the ability of the epithelium to respond to injury.

Oral tolerance

The immune system must guard against pathogens and toxins while avoiding an excessive response to the multiplicity of food antigens and commensal bacteria. The mechanisms by which tolerance occurs are undoubtedly multiple, including maintaining barrier function to prevent excess antigen uptake, active inhibition via regulatory T cells, and dendritic cells which promote tolerogenic rather than immunogenic T cell responses. All of these are likely to play a role in diseases such as coeliac disease, caused by an excessive T cell response to gluten, or Crohn's disease, where tolerance to the indigenous bacterial population is defective.

Presenting features of small bowel disease

Regardless of the cause, the common presenting features of small bowel disease are listed below. However, 10–20% of patients will have no diarrhoea or any other gastrointestinal symptoms.

FURTHER READING

Abrahams C, Medzhitov R. Interactions between the host innate immune system and microbes in inflammatory bowel disease. *Gastroenterology* 2011; 140: 1720–1728.

- **Diarrhoea** is common and may be watery.
- **Steatorrhoea** occurs when the stool fat is >17 mmol/day (or 6 g/day). The stools are pale, bulky, offensive, float (because of their increased air content), leave a fatty film on the water in the pan and are difficult to flush away.
- **Abdominal pain** and discomfort. Abdominal distension can cause discomfort and flatulence. The pain has no specific character or periodicity and is not usually severe.
- **Weight loss.** Weight loss is largely due to the anorexia that invariably accompanies small bowel disease. The calorie deficit due to malabsorption is small relative to the reduction in intake.
- **Nutritional deficiencies.** Deficiencies of iron, B₁₂, folate or all of these, leading to anaemia, are the only common deficiencies. Occasionally malabsorption of other vitamins or minerals occurs, causing bruising (vitamin K deficiency), tetany (calcium deficiency), osteomalacia (vitamin D deficiency), or stomatitis, sore tongue and aphthous ulceration (multiple vitamin deficiencies). Oedema due to hypoproteinaemia is due to low intake and intestinal loss of albumin (protein-losing enteropathy).

Physical signs are few and nonspecific. If present, they are usually associated with anaemia and the nutritional deficiencies described above.

Abdominal examination is often normal, but sometimes distension and, rarely, hepatomegaly or an abdominal mass are found. Visible peristalsis and high pitched bowel sounds can indicate chronic subacute obstruction of the small intestine, e.g. due to stricturing Crohn's disease. Gross weight loss, oedema and muscle wasting is seen only in severe cases. A neuropathy, not always due to B₁₂ deficiency, can be present.

Investigation of small bowel disease

(Fig. 6.27)

The emphasis in the investigation of malabsorption is on the structural features of the underlying disorder, rather than on the documentation of malabsorption itself.

Blood tests

- **Full blood count and film.** Anaemia can be microcytic, macrocytic or normocytic and the blood film may be dimorphic. Other abnormal cells (e.g. Howell-Jolly bodies, p. 406) may be seen in splenic atrophy associated with coeliac disease.
 - Serum ferritin and iron saturation should be measured to differentiate iron deficiency from anaemia of chronic disorder (see p. 380). Remember ferritin is an acute phase protein and is therefore difficult to interpret in the context of an inflammatory response for any reason.
 - Serum B₁₂, and serum and red cell folate should be measured.
 - Red cell folate is a good indicator of the presence of small bowel disease. It is frequently low in both coeliac disease and Crohn's disease, which are the two most common causes of small bowel disease in developed countries.
- **Low serum calcium** and raised alkaline phosphatase may indicate the presence of osteomalacia due to vitamin D deficiency.

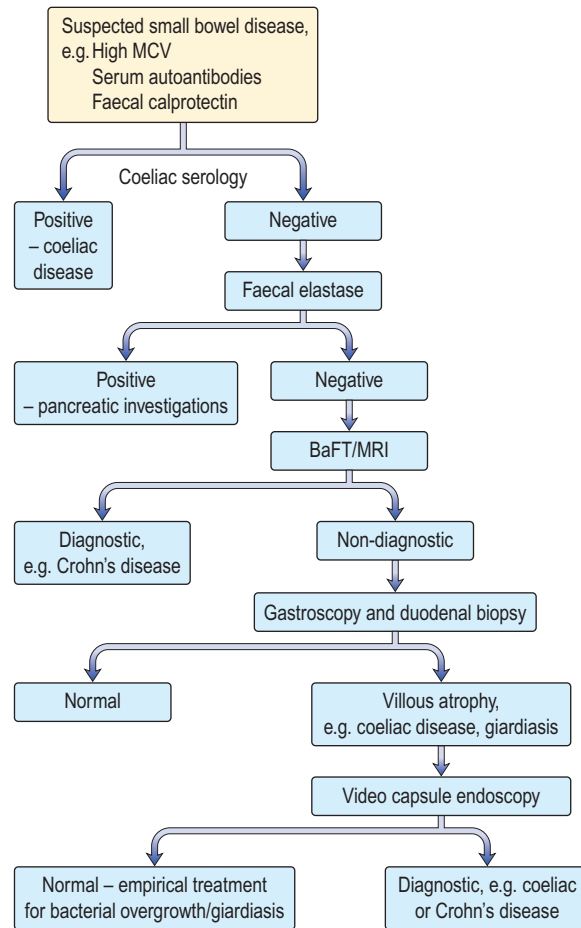

Figure 6.27 Flow diagram for investigation of patients with suspected small bowel disease. BaFT, barium follow-through; MRI, magnetic resonance imaging.

- **Liver biochemistry** and serum albumin and prothrombin time.
- **Immunological tests.** Measurement of serum antibodies to endomysium and tissue transglutaminase is useful for the diagnosis of coeliac disease. These should always be accompanied by an assessment of total immunoglobulin levels.
- **HLA testing** is useful in coeliac disease.

Small bowel anatomy

- **MRI enteroclysis.** This is cross-sectional imaging which does not involve radiation. Using oral loading with water or a hyperosmotic solution to distend the small bowel lumen.
- **Small bowel barium follow-through** (see p. 234). This detects gross anatomical defects such as diverticula, strictures and Crohn's disease. Dilatation of the bowel and a changed fold pattern may suggest malabsorption but these are nonspecific findings. Gross dilatation is seen in myopathic pseudo-obstruction.
- **Small bowel biopsy.** This is used to assess the microanatomy of the small bowel mucosa. Biopsies are usually obtained via an endoscope passed into the duodenum and should be well-orientated for correct evaluation. The histological appearances are described in the sections on individual diseases. A smear of the jejunal juice or a mucosal impression should also be made when *Giardia intestinalis* is suspected.

- **Ultrasound** is a useful preliminary investigation which can show thickened small bowel or distended loops.
- **CT scanning** is used to look for small bowel wall thickening, diverticula and for extraintestinal features such as abscesses (e.g. in Crohn's disease).
- **Video-capsule enteroscopy** is increasingly widely used to directly visualize the small bowel lumen and mucosa along its entire length. It is particularly useful in the diagnosis of occult GI bleeding.

Tests of absorption

These are required only in *complicated* cases.

- **Fat malabsorption.** The confirmation of the presence of steatorrhoea is only occasionally necessary. Three-day faecal fat analysis, triglyceride breath tests and serum β carotene are now rarely performed. In rare cases when it is essential to confirm steatorrhoea, Sudan III staining of a faecal sample can be used.
- **Lactose tolerance test.** Testing is of little use in adults because lactose intolerance is rarely a clinical problem; patients who are upset by milk usually avoid it. Formal testing involves giving an oral dose of 50 g of lactose and serial measurement of blood glucose over 2 hours. (Note: 500 mL of milk contain 20 g of lactose). There is a high incidence of lactase deficiency in many parts of the world (e.g. the Mediterranean countries, and parts of Africa and Asia).

Other tests

- **Hydrogen breath test.** This is frequently used as a screening test to measure transit time and to detect small bowel bacterial overgrowth. Bacteria are present in the oral cavity so the mouth should be rinsed out with an antiseptic mouthwash beforehand. The appearance of a breath hydrogen peak after oral lactulose is used to estimate mouth to caecum transit time. An earlier rise in the breath hydrogen after lactulose indicates bacterial breakdown in the small intestine. This test is simple to perform and it does not involve radioisotopes. However, interpretation is often difficult with a low sensitivity and specificity.
- **Tests for pancreatic insufficiency** are used in the differential diagnosis of steatorrhoea. Human pancreatic elastase 1 (E1) remains undegraded during intestinal transit so its concentration in faeces reflects exocrine pancreatic function. The faecal elastase test quantifies E1 in stool, allowing the diagnosis or exclusion of severe pancreatic exocrine insufficiency (see p. 360).
- **Other blood tests.** Serum immunoglobulins are measured to exclude immune deficiencies in particular IgA deficiency which may lead to false-negative coeliac antibody tests. Gut peptides (e.g. VIP) are measured in high-volume secretory diarrhoea, and chromogranins A and B are raised in endocrine tumours.
- **Tests for protein-losing enteropathy (PLE)** (see p. 234). These tests are rarely required unless a low serum albumin is a major clinical feature.
- **Measurement of α_1 antitrypsin clearance** does not require an isotope. α_1 antitrypsin is a large molecule (>50 000 daltons), which is resistant to proteolysis. Simultaneous measurements of serum and stool concentration (24-hour collection) are made.
- **Bile salt loss.** This can be demonstrated by giving oral ^{75}Se -homocholyl taurine (SeHCAT – a synthetic taurine

Table 6.9 Disorders of the small intestine causing malabsorption

Parasite infestation (e.g. <i>Giardia intestinalis</i>)

conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days.

- **Stool tests.** Faecal calprotectin is 93% sensitive and 96% specific for IBD. Faecal lactoferrin is also an inflammatory marker.

Malabsorption

In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not usually dominate the clinical picture. An example is Crohn's disease, in which malabsorption of vitamin B₁₂ can be demonstrated, but this is not usually the major problem; diarrhoea and general ill-health are the major features.

The major disorders of the small intestine that cause malabsorption are shown in Table 6.9.

Coeliac disease (gluten-sensitive enteropathy)

Coeliac disease (CD) is a condition in which there is inflammation of the mucosa of the upper small bowel that improves when gluten is withdrawn from the diet and relapses when gluten is reintroduced. Up to 1% of many populations are affected, though most have clinically silent disease.

Aetiology

Gluten is the entire protein content of the cereals wheat, barley and rye. Prolamins (gliadin from wheat, hordeins from barley, secalins from rye) are damaging factors. These proteins are resistant to digestion by pepsin and chymotrypsin because of their high glutamine and proline content and remain in the intestinal lumen triggering immune responses.

Immunology. Gliadin peptides pass through the epithelium (para- and/or intracellularly) and are deaminated by tissue transglutaminase which increases their immunogenicity. Gliadin peptides then bind to antigen-presenting cells which interact with CD4⁺ T cells in the lamina propria via HLA class II molecules DQ2 or DQ8. These T cells produce pro-inflammatory cytokines, particularly interferon- γ . CD4⁺ T cells also interact with B cells to produce endomysial and tissue transglutaminase antibodies. Gliadin peptides also cause release of interleukin-15 from enterocytes, activating intra-epithelial lymphocytes with a natural killer cell marker. This inflammatory cascade releases metalloproteinases and other mediators that contribute to the villous atrophy and crypt hyperplasia which are typical of the disease.

The mucosa of the proximal small bowel is predominantly affected, the mucosal damage decreasing in severity towards the ileum as gluten is digested into smaller 'non-toxic' fragments.

Genetic factors. There is an increased incidence of coeliac disease within families but the exact mode of inheritance is unknown; 10–15% of 1st-degree relatives will have

Hunt KA, van Heel DA. Recent advances in coeliac disease genetics. *Gut* 2009; 58:473–476.

the condition, although it may be asymptomatic. The concordance rate in identical twins is about 70%.

HLA-DQ2 (DQA1*0501, DQB1*0201) and HLA-DQ8 (DQA1*0301, DQB1*0302) are associated with CD. Over 90% of patients will have HLA-DQ2, compared with 20–30% of the general population. Studies in twins and siblings indicate that HLA genes are responsible for <50% of the genetic cause of the disease. Many unaffected people also carry these genes, so other factors must also be involved. Non-HLA genes may also contribute to coeliac disease, e.g. chromosome regions 19p13.1, 11q, 5q31–33 and 6q21–22. The CD28/CTLA4/IL05 gene cluster has also shown linkage with coeliac disease.

Environmental factors. Breast-feeding and the age of introduction of gluten into the diet are significant.

Rotavirus infection in infancy also increases the risk, and adenovirus-12 which has sequence homology with α -gliadin has been suspected as a causative agent but this is now thought to be unlikely.

Clinical features

Coeliac disease can present at any age. In infancy it sometimes appears after weaning onto gluten-containing foods. The peak period for diagnosis in adults is in the 5th decade, with a female preponderance. Many patients are asymptomatic (silent) and come to attention because of routine blood tests, e.g. a raised MCV, or iron deficiency in pregnancy. The symptoms are very variable and often nonspecific, e.g. tiredness and malaise often associated with anaemia.

GI symptoms may be absent or mild. Coeliac disease should be tested for in all patients with symptoms suggestive of IBS. Diarrhoea or steatorrhoea, abdominal pain and weight loss suggest more severe disease. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression occur.

Rare complications include tetany, osteomalacia or gross malnutrition with peripheral oedema. Neurological symptoms such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness or a polyneuropathy occur; the prognosis for these symptoms is variable. There is an increased incidence of atopy and autoimmune disease, including thyroid disease, type 1 diabetes and Sjögren's syndrome. Other associated diseases include inflammatory bowel disease, primary biliary cirrhosis, chronic liver disease, interstitial lung disease and epilepsy. IgA deficiency is more common than in the general population. Long-term problems include osteoporosis which occurs even in patients on long-term gluten-free diets.

Physical signs are usually few and nonspecific and are related to anaemia and malnutrition.

Diagnosis

Small bowel biopsy is still considered 'gold standard' for positive diagnosis, and is therefore desirable in all but the most clear-cut cases, because treatment involves a life-long diet that is both expensive and socially limiting. However with the increasing accuracy of serological tests, it is no longer necessary to take duodenal biopsies for suspected coeliac disease in patients without antibodies. For example in patients being endoscoped for iron deficiency anaemia with negative coeliac serology, the pretest value of small bowel histology is <0.03%.

If biopsies are to be taken, because the disease is sometimes patchy and it can be difficult to orientate endoscopic biopsies for histological section, four to six forceps biopsies should be taken from the second part of the duodenum.

Endoscopic signs including absence of mucosal folds, mosaic pattern of the surface and scalloping of mucosal folds are often present; however, their absence is not conclusive because they are markers of relatively severe disease.

Histology (Fig. 6.28). Histological changes are of variable severity and, though characteristic, are not specific. Villous atrophy can be caused by many other conditions, but coeliac disease is the commonest cause of subtotal villous atrophy.

Histological examination shows crypt hyperplasia with chronic inflammatory cells in the lamina propria, and villous atrophy. The enterocytes become cuboidal with an increase in the number of intraepithelial lymphocytes. In the lamina propria there is an increase in lymphocytes and plasma cells. The most severe histological change with mucosal atrophy and hypoplasia is seen in patients who do not respond to a gluten-free diet.

In mild cases, the villous architecture is almost normal but there are increased numbers of intraepithelial lymphocytes.

Serology. Persistent diarrhoea, folate or iron deficiency, a family history of coeliac disease and associated autoimmune disease are indications for serological testing.

The most sensitive tests are for endomysial and anti-tissue transglutaminase antibodies. The sensitivity of these tests is >90% though both are not always positive in the same subject. Titres of either correlate with the severity of mucosal damage so they can be used for dietary monitoring. Standard tests use IgA class antibodies. Selective IgA deficiency occurs in 2.5% of coeliac disease patients but only 0.25% of normals and renders these tests falsely negative. All patients should have concomitant IgA levels tested and if deficient, IgG-based tests should then be used.

HLA typing. HLA-DQ2 is present in 90–95% of CD patients and HLA-DQ8 in about 8%, i.e. most of the rest. The absence of both alleles has a high negative predictive value for coeliac disease. HLA typing may occasionally be useful for risk assessment, e.g. in patients already on a gluten free diet.

Other investigations

- **Haematology.** Mild or moderate anaemia is present in 50% of cases. Folate deficiency is common, often causing macrocytosis. B₁₂ deficiency is rare. Iron deficiency due to malabsorption of iron and increased loss of desquamated cells is common. A blood film may therefore show microcytes and macrocytes as well as hypersegmented polymorphonuclear leucocytes and Howell–Jolly bodies (see p. 406) due to splenic atrophy.
- **Biochemistry, liver biochemistry and function.** In severe cases, biochemical evidence of osteomalacia may be seen (low calcium and high phosphate) and hypoalbuminaemia.
- **Radiology.** A small bowel follow-through may show dilatation of the small bowel with slow transit. Folds become thicker and in severe disease total effacement is seen. Radiology is mainly used when a complication, e.g. lymphoma, is suspected.
- **Bone densitometry** (DXA) should be performed on all patients because of the risk of osteoporosis.
- **Capsule endoscopy** (see p. 233) is used to look for gut abnormalities when a complication is suspected.

Treatment and management

Replacement minerals and vitamins, e.g. iron, folic acid, calcium, vitamin D, may be needed initially to replace body stores.

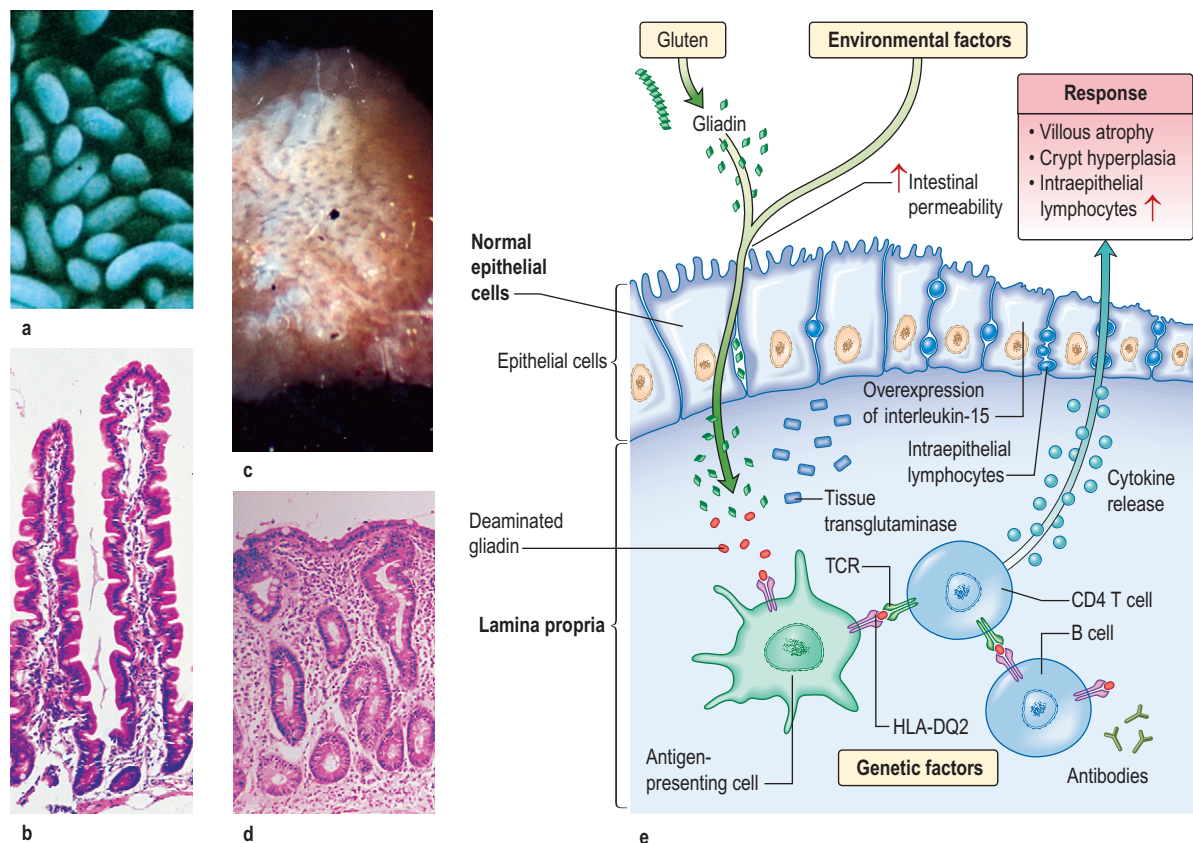

Figure 6.28 Small bowel mucosal appearances – macroscopic and microscopic. (a) Normal mucosa under the dissecting microscope (DM). (b) Normal mucosal histology. (c) Coeliac disease – flattened mucosa. (d) Coeliac disease – showing subtotal villous atrophy. (e) Immune and genetic mechanisms in coeliac disease. TCR, T cell receptor. (After Green PH, Cellier C. Coeliac disease. *New England Journal of Medicine* 2007; 357:1731–1743.)

Treatment is with a gluten-free diet for life. Dietary elimination of wheat, barley and rye usually produces a clinical improvement within days or weeks. Morphological improvement often takes months, especially in adults. Oats are tolerated by most coeliacs, but must not be contaminated with flour during their production. Meat, dairy products, fruits and vegetables are naturally gluten free and are all safe.

Gluten-free products can be expensive, unless subsidized by national health services. Patient support organizations such as The Coeliac Society are valuable as information sources and for advice about diet, recipes and gluten-free processed foods. Despite advice, many patients do not keep to a strict diet but maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis can occur even in treated cases.

The usual cause for *failure to respond* to the diet is poor compliance. Dietary adherence can be monitored by serial tests for endomysial antibody (EMA) and tissue transglutaminase (tTG). If clinical progress is suboptimal then a repeat intestinal biopsy should be taken. If the diagnosis is equivocal on the diagnostic mucosal biopsy, or if the patient has already started on a gluten-free diet, then a gluten challenge, i.e. reintroduction of oral gluten, with evidence of jejunal morphological change, can confirm the diagnosis.

Patients should have *pneumococcal vaccinations* (because of splenic atrophy) once every 5 years (see p. 406).

Complications

A few patients do not improve on a strict diet and are said to have *non-responsive coeliac disease*. Many of these patients are still ingesting gluten (see above). A few of the others may

have concomitant problems, e.g. microscopic colitis, IBD, small bowel bacterial overgrowth or lactase deficiency.

A very small percentage will have the rare complication of **refractory coeliac disease** (RCD). In type 1 RCD, the lymphocytes are normal and the T cell receptors are polyclonal, whilst in type 2 there are abnormal clonal lymphocytes with loss of CD8 and CD3 surface markers. The 5-year survival rates are 93% and 40–60% respectively.

Very rarely, enteropathy-associated **T cell lymphoma** (EATCL) (8–20% 5-year survival), or ulcerative jejunitis can occur as part of a spectrum of neoplastic T cell disorders. Small bowel adenocarcinoma is also increased in coeliac disease.

Ulcerative jejunitis presents with fever, abdominal pain, perforation and bleeding.

Diagnosis for these conditions is with MRI or barium studies but laparoscopy with full-thickness small bowel biopsies is often required. Steroids and immunosuppressive agents, e.g. azathioprine, are used in ulcerative jejunitis.

Carcinoma of the oesophagus as well as extragastrointestinal cancers are also increased in incidence. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

Dermatitis herpetiformis

This is an uncommon blistering subepidermal eruption of the skin associated with a gluten-sensitive enteropathy (see also p. 1222). Rarely gross malabsorption occurs, but usually the jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological

abnormalities are the same as for coeliac disease. The skin condition responds to dapsone but a gluten-free diet improves both the enteropathy and the skin lesion, and is recommended for long-term benefit.

Tropical sprue

This is a condition presenting with chronic diarrhoea and malabsorption that occurs in residents or visitors to affected tropical areas. The disease is endemic in most of Asia, some Caribbean islands, Puerto Rico and parts of South America. Epidemics occur, lasting up to 2 years, and in some areas repeated epidemics occur at varying intervals of up to 10 years.

The term tropical sprue is reserved for severe malabsorption (of two or more substances) accompanied by diarrhoea and malnutrition. Malabsorption of a mild degree, sometimes following an enteric infection, is quite common in the tropics; it is usually asymptomatic and is sometimes called tropical malabsorption.

Aetiology

The aetiology is unknown, but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics. A number of agents have been suggested but none has been unequivocally shown to be responsible. Different agents could be involved in different parts of the world.

Clinical features

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency. The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

Diagnosis

Acute infective causes of diarrhoea must be excluded (see p. 293), particularly *Giardia*, which can produce a syndrome very similar to tropical sprue. Malabsorption should be demonstrated, particularly of fat and B₁₂. The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases, the lesion is less severe than that found in coeliac disease, although it affects the whole small bowel. Mild mucosal changes can be seen in asymptomatic individuals in the tropics.

Treatment and prognosis

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most patients also require an antibiotic to ensure a complete recovery (usually tetracycline 1 g daily for up to 6 months).

Severely ill patients require resuscitation with fluids and electrolytes for dehydration, and nutritional deficiencies should be corrected. Vitamin B₁₂ (1000 µg) is also given to all acute cases.

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

Bacterial overgrowth

The gut contains many resident bacteria in the terminal ileum and colon. Anaerobic bacteria, e.g. *Bacteroides*, bifidobacteria, are 100–1000 times more abundant than aerobic

(facultative anaerobes), e.g. *Escherichia*, *Enterobacter*, *Enterococcus*. This gut microflora has major functions including metabolic, e.g. fermentation of non-digestible dietary residues into short-chain fatty acids as an energy source in the colon.

The microflora which influences epithelial cell proliferation, is involved in the development and maintenance of the immune system and protects the gut mucosa from colonization by pathogenic bacteria. Bacteria also initiate vitamin K production.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills some ingested organisms and intestinal motility keeps bacterial counts in the jejunum low. The normal terminal ileum contains faecal-type organisms, mainly *Escherichia coli* and anaerobes, and the colon has abundant bacteria.

Bacterial overgrowth is normally found associated with a structural abnormality of the small intestine such as a stricture or diverticulum, although it can occur occasionally in the elderly without. *E. coli* and/or *Bacteroides*, both in concentrations greater than 10⁶/mL, are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylating bile salts, so that unconjugated and dehydroxylated bile salts can be detected in small bowel aspirates.

Clinical features

The clinical features of overgrowth are chiefly diarrhoea and steatorrhoea. There may also be symptoms due to the underlying small bowel pathology. Steatorrhoea (see p. 263) occurs because of conjugated bile salt deficiency. Some bacteria can metabolize vitamin B₁₂ and interfere with its binding to intrinsic factor, leading to mild B₁₂ deficiency (see Chapter 8) rarely severe enough to produce a neurological deficit. Some bacteria produce folic acid giving a high serum folate. Bacterial overgrowth has only minimal effects on the absorption of other substances. Confirmation of bacterial overgrowth is with the hydrogen breath test (see p. 264).

Treatment

If possible, the underlying lesion should be corrected (e.g. a stricture should be resected). Where this is not possible, rotating courses of antibiotics are necessary, such as metronidazole, a tetracycline or ciprofloxacin. The response to antibiotics is unpredictable.

Intestinal resection

Small intestinal resection is usually well tolerated, but massive resection leaving <1 m of small bowel in continuity is followed by the *short-bowel syndrome*. The effects of resection depend on the amount and location of the resection and the presence or absence of the colon. Resection of the jejunum is better tolerated than ileal resection, where there is less adaptation, probably due to low levels of glucagon-like peptide 2 (GLP-2), which is a specific growth hormone for the enterocyte.

Ileal resection

The ileum is the site of specific mechanisms for the absorption of bile salts and vitamin B₁₂. Relatively small resections lead to malabsorption of these substances. Removal of the ileocaecal valve increases the incidence of diarrhoea (Fig. 6.29).

The following occur after ileal resection:

- **Bile-salt induced diarrhoea:** bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes (see p. 293).

Figure 6.29 The effects of resection of distal small bowel.

- **Steatorrhoea and gallstone formation:** increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micelle formation and steatorrhoea, and lithogenic bile and gallstone formation.
- **Oxaluria and oxalate stones:** bile salts in the colon cause increased oxalate absorption with oxaluria leading to urinary stone formation.
- **B₁₂ deficiency:** low serum B₁₂, macrocytosis and other effects of B₁₂ deficiency.

Investigations include a small bowel follow-through, measurement of B₁₂, bile salt retention (SeHCAT) test (see p. 236). A hydrogen breath test may show rapid transit (see p. 264). Many patients require B₁₂ replacement and some need a low-fat diet if there is steatorrhoea. Diarrhoea is often improved by cholestyramine which binds bile salts and reduces the level of diarrhoeogenic bile salts in the colon.

Jejunal resection

The ileum can compensate for loss of jejunal absorptive function. Jejunal resection may lead to gastric hypersecretion with high gastrin levels; the exact mechanism of this is unclear. Structural and functional intestinal adaptation takes place over the course of a year, with an increase in the absorption per unit length of bowel.

Massive intestinal resection (short-bowel syndrome)

Intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption and is characterized by the inability to maintain protein-energy, fluid, electrolyte, or micronutrient balance. This most often occurs following resection for Crohn's disease, mesenteric vessel occlusion (see p. 270), radiation enteritis (see p. 268) or trauma. There are two common situations:

Shortened small intestine ending at a terminal small bowel stoma

The major problem is of sodium and fluid depletion, and the majority of patients with ≤ 100 cm of jejunum remaining will require parenteral supplements of fluid and electrolytes, often with nutrients. Sodium losses can be minimized by increasing salt intake, restricting hypotonic fluids between meals and administering oral glucose-electrolyte mixture with a sodium concentration 90 mmol/L. Jejunal transit time can be increased and stomal effluent loss reduced by treatment with the somatostatin analogue octreotide, often used in combination with a proton pump inhibitor, loperamide and codeine phosphate. There is no benefit from a low-fat diet, but fat assimilation can be increased on treatment with cholestyramine and synthetic bile acids.

Shortened small intestine in continuity with colon

Because of the absorptive capacity of the colon for fluid and electrolytes, only a small proportion of these patients require parenteral supplementation. Unabsorbed fat results in impairment of colonic fluid and electrolyte absorption so patients should be on a low-fat diet. A high carbohydrate intake is advised as unabsorbed carbohydrate is metabolized anaerobically to short-chain fatty acids (SCFAs) which are absorbed; they also stimulate fluid and electrolyte absorption in the colon and act as an energy source (1.6 kcal/g). Patients are often treated with cholestyramine to reduce diarrhoea and colonic oxalate absorption.

Whipple's disease

Whipple's disease is a rare infectious bacterial disease caused by *Tropheryma whippelii*. About 1000 cases have been described; 87% are males, usually white and middle-aged. It presents with arthritis and arthralgia, progressing over years to weight loss and diarrhoea with abdominal pain, systemic symptoms of fever and weight loss. Peripheral lymphadenopathy and involvement of the heart, lung, joints and brain occur, simulating many neurological conditions.

Blood tests show features of chronic inflammation and malabsorption. Endoscopy typically shows pale, shaggy duodenal mucosa with eroded, red, friable patches.

Diagnosis is made by small bowel biopsy. Periodic acid-Schiff (PAS)-positive macrophages are present but are nonspecific. On electron microscopy, the characteristic trilaminar cell wall of *T. whippelii* can be seen within macrophages. *T. whippelii* antibodies can be identified by immunohistochemistry. A confirmatory PCR-based assay is available.

Treatment is with antibiotics which cross the blood-brain barrier, such as 160 mg trimethoprim and 800 mg sulphamethoxazole (co-trimoxazole) daily for 1 year. This is preceded by a 2-week course of streptomycin and penicillin or ceftriaxone. Treatment periods of less than a year are associated with relapse in about 40%.

Radiation enteritis

Radiation of >40 Gy will damage the intestine. The chronic effects of radiation are muscle fibre atrophy, ulcerative changes due to ischaemia and obstruction due to radiation-induced fibrotic strictures.

Pelvic irradiation is frequently used for gynaecological and urinary tract malignancies, so the ileum and rectum are the areas most often involved.

FURTHER READING

Fenollar F, Puéchal X, Raoult D. Whipple's disease (review). *N Engl J Med* 2007; 356:55–66.

At the time of the irradiation, there may be nausea, vomiting, diarrhoea and abdominal pain, usually improving within 6 weeks of completion of therapy.

Chronic radiation enteritis is diagnosed if symptoms persist for ≥ 3 months. The prevalence is $>15\%$. Abdominal pain due to obstruction is the main symptom. Malabsorption can be due to bacterial overgrowth in dilated segments and mucosal damage.

Many patients suffer from increased bowel frequency.

Treatment is symptomatic, although often unsuccessful in chronic radiation enteritis. Surgery should be avoided if possible, being reserved for obstruction or perforation.

Acute radiation damage to the rectum produces a *radiation proctitis* with diarrhoea and tenesmus, with or without blood. Local steroids sometimes help initially. When the acute phase heals, mucosal telangiectases form and may cause persistent bleeding. They can be treated with argon plasma coagulation or, under a light anaesthetic, by packing the rectum with a formalin-soaked swab for 2 min, both of which destroy the telangiectases.

Parasite infestation

Giardia intestinalis (see p. 151) not only produces diarrhoea but can produce malabsorption with steatorrhoea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.

Cryptosporidiosis (see p. 151) can also produce malabsorption.

Patients with HIV infection are particularly prone to parasitic infestation (see Table 6.23).

Other causes of malabsorption

- **Drugs that bind bile salts** (e.g. cholestyramine) and some antibiotics (e.g. neomycin) produce steatorrhoea.
- **Orlistat** (see p. 220) is used in obesity to reduce fat absorption by inhibiting gastric and pancreatic lipase causing diarrhoea and steatorrhoea.
- **Thyrotoxicosis**: diarrhoea, rarely with steatorrhoea, occurs in thyrotoxicosis owing to increased gastric emptying and increased motility.
- **Zollinger–Ellison syndrome** (see p. 370).
- **Intestinal lymphangiectasia** produces diarrhoea and rarely steatorrhoea (see p. 270).
- **Lymphoma** that has infiltrated the small bowel mucosa causes malabsorption.
- **Diabetes mellitus**: diarrhoea, malabsorption and steatorrhoea occur, sometimes due to bacterial overgrowth from autonomic neuropathy causing small bowel stasis.
- **Hypogammaglobulinaemia**, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhoea due either to an abnormal jejunal mucosa or to secondary infestation with *Giardia intestinalis*.

Miscellaneous intestinal diseases

Protein-losing enteropathy

Protein-losing enteropathy refers to intestinal conditions causing protein loss, usually manifest by hypoalbuminaemia. The causes include Crohn's disease, tumours, Ménétrier's disease, coeliac disease and lymphatic disorders (e.g. lymphangiectasia).

Usually protein-losing enteropathy forms a minor part of the generalized disorder, but occasionally hepatic synthesis of albumin cannot compensate for the protein loss, and peripheral oedema dominates the clinical picture. The investigations are described on page 264 and treatment is that of the underlying disorder.

Meckel's diverticulum

This is the most common congenital abnormality of the GI tract, affecting 2–3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless, but 50% contain gastric mucosa that secretes hydrochloric acid. Peptic ulcers can occur and may bleed (see p. 254) or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Obstruction from an associated band rarely occurs.

Treatment is surgical removal, often laparoscopically.

Tuberculosis

Tuberculosis (TB) (see also p. 839) can affect the intestine as well as the peritoneum (see p. 302). In developed countries, most patients are from ethnic minority groups, or are immunocompromised due to HIV or drugs. Intestinal tuberculosis is due to reactivation of primary disease caused by *Mycobacterium tuberculosis*. Bovine TB occurs in areas where milk is unpasteurized and is rare in western countries.

Clinical features are abdominal pain, weight loss, anaemia, fever with night sweats, obstruction, right iliac fossa pain or a palpable mass. The ileocaecal area is most commonly affected, but the colon, and rarely other parts of the gastrointestinal tract, can be involved. One-third of patients present acutely with intestinal obstruction or generalized peritonitis; 50% have X-ray evidence of pulmonary tuberculosis.

Diagnosis

Differential diagnosis includes Crohn's disease and caecal carcinoma.

- A small bowel follow-through may show transverse ulceration, diffuse narrowing of the bowel with shortening of the caecal pole.
- Ultrasound or CT shows additional mesenteric thickening and lymph node enlargement.
- Histology and culture of tissue is desirable, but it is not always possible. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases.

Treatment

Drug treatment is similar to that for pulmonary TB (see page 842). Treatment should be started if there is a high degree of suspicion.

Amyloid

Systemic amyloidosis may affect any part of the GI tract (see also p. 1042). Rectal biopsy may be diagnostic. Occasionally, amyloid deposits occur as polypoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

Rheumatic autoimmune disorders

Systemic sclerosis (see p. 538) most commonly affects the oesophagus (see p. 243), although the small bowel and

Protein-losing enteropathy.

colon are often found to be involved if investigated. There may be no symptoms of this involvement, but diarrhoea and steatorrhoea can occur due to bacterial overgrowth as a result of reduced motility, dilatation and the presence of diverticula.

Intestinal ischaemia

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow or failure of perfusion; these factors may act alone or in combination and usually occur in the elderly.

Arterial inflow occlusion can be caused by atheroma, thrombosis, and embolism (cardiac arrhythmia), including cholesterol emboli (see p. 599), aortic disease (occluding ostia of mesenteric vessels) or vasculitis (see p. 542), thromboangiitis and Takayasu's syndrome (see p. 745)

Venous outflow occlusion occurs in 5–15% of cases and usually in sick patients with circulatory failure.

Infarction without occlusion can occur due to reduced cardiac output, hypotension and shock causing reduced intestinal blood flow.

Acute small intestinal ischaemia

An embolus from the heart in a patient with atrial fibrillation is the commonest cause, usually occluding the superior mesenteric artery. Patients present with sudden abdominal pain and vomiting with a distended and tender abdomen, and absent bowel sounds. The patient is hypotensive and ill. Surgery is necessary to resect the gangrenous bowel. Mortality is high (up to 90%) and is related to co-existing disease, the development of multiorgan failure (MOF) (see p. 882) and massive fluid and electrolyte losses in the postoperative period. Survivors may go on to develop nutritionally inadequate short-bowel syndrome (see p. 268).

Ischaemic colitis

See page 285.

Chronic small intestinal ischaemia

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, particularly in the elderly. Good collateral circulation can minimize clinical effects. The characteristic symptom is post-prandial abdominal pain and weight loss. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography.

Eosinophilic gastroenteritis

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved either as a localized lesion (eosinophilic granuloma) or diffusely with sheets of eosinophils seen in the serosal and submucosal layers. There is an association with asthma, eczema and urticaria.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involvement. Abdominal pain, nausea and vomiting and upper GI bleeding occur. Peripheral eosinophilia occurs in only 20% of patients. Endoscopic biopsy is useful for making the diagnosis histologically. Radiology may demonstrate mass lesions.

Treatment is with corticosteroids for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults, the condition appears to be allergic (allergic gastroenteritis) and is associated with peripheral eosinophilia and high levels of plasma and tissue IgE. Eosinophilic oesophagitis's relationship to eosinophilic gastroenteritis is unclear.

Intestinal lymphangiectasia

Dilatation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. Hypoproteinaemia with ankle oedema is the main feature. The rare primary form may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. White-tipped villi are seen on capsule endoscopy. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Treatment is with a low-fat diet, mid-chain triglycerides and fat-soluble vitamin supplements as required. Octreotide has a dramatic effect in a few primary cases, although the mechanism of action is unknown.

Abetalipoproteinaemia

This rare congenital disorder is due to a failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, giving a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

Tumours of the small intestine

The small intestine is relatively resistant to the development of neoplasia and only 3–6% of all GI tumours and fewer than 1% of all malignant lesions occur here. The reason for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

Adenocarcinoma of the small intestine is rare and found most frequently in the duodenum (in the periampullary region) and in the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

Lymphomas are most frequently found in the ileum. These are of the non-Hodgkin's type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In developed countries, the most common type of lymphoma is the B cell type arising from MALT (see p. 468). These lymphomas tend to be annular or polypoid masses in the distal or terminal ileum, whereas most T cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt's lymphoma also occurs and commonly affects the terminal ileum of children in North Africa and the Middle East.

Predisposing factors for adenocarcinoma and lymphoma

Coeliac disease

There is an increased incidence of lymphoma of the T cell type and adenocarcinoma of the small bowel, as well as

an unexplained increase in all malignancies both in the GI tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a premalignant condition, but there is no association with the length of the symptoms. Treatment with a gluten-free diet reduces the risk of both lymphoma and carcinoma.

Crohn's disease

There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn's disease.

Immunoproliferative small intestinal disease (IPSID)

IPSID is a rare B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel producing truncated monoclonal heavy chains, without associated light chains. The α heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. It occurs usually in countries surrounding the Mediterranean, but it has also been found in other developing countries in South America and the Far East. IPSID predominantly affects people in lower socioeconomic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes, progressing in some cases to a lymphoma. The condition has also been documented in the developed world.

Clinically, patients present with abdominal pain, diarrhoea, anorexia, weight loss and symptoms of anaemia. There may be a palpable mass, and a small bowel follow-through may detect a mass lesion. Endoscopic biopsy is useful where lesions are within reach. Ultrasound and CT may show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy can be used where obstruction by the capsule is not likely, but cannot deliver histology.

Treatment of small intestinal tumours

Adenocarcinoma. Most patients are treated surgically with a segmental resection. The overall 5-year survival rate is 20–35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

IPSID. If there is no evidence of lymphoma, antibiotics, e.g. tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series the 3–5-year survival rate was 58%.

Lymphoma. Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type. The 5-year survival rate for T cell lymphomas is 25%, but is better for B cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

Carcinoid tumours

These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being in the appendix and terminal ileum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. A total of 10% of carcinoid tumours in the appendix present as acute appendicitis, secondary to obstruction. Surgical resection of the tumour is usually performed.

Most carcinoids do not secrete hormones or vasoactive compounds, and may present with liver enlargement due to metastases.

Carcinoid syndrome occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck, sometimes leading to permanent changes with telangiectases.

Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and consist of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals hepatomegaly. The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxy-tryptamine – 5-HT), bradykinin, histamine, tachykinins and prostaglandins. The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin. This is known to cause vasodilatation, bronchospasm and increased intestinal motility.

Diagnosis and treatment of carcinoid syndrome

- **Ultrasound examination** confirms the presence of liver secondary deposits.
- **Urine** shows a high concentration of 5-hydroxyindoleacetic acid (5-HIAA) which is the major metabolite of 5-HT.
- **Serum chromogranin A** is raised in nearly all hindgut tumours and 80–90% of patients with symptomatic foregut and midgut tumours.

Treatment is with octreotide and lanreotide; both are octapeptide somatostatin analogues that inhibit the release of many gut hormones. They alleviate the flushing and diarrhoea and can control a carcinoid crisis. Octreotide is given subcutaneously in doses up to 200 μ g three times daily initially; a depot preparation 30 mg every 4 weeks can then be used. Lanreotide 30 mg is given every 7–10 days or as a gel 60 mg every 28 days. Long-acting octreotide also sometimes inhibits tumour growth. Interferon and other chemotherapeutic regimens also occasionally reduce tumour growth, but have not been shown to increase survival.

Most patients survive for 5–10 years after diagnosis.

Peutz-Jeghers syndrome

This consists of mucocutaneous pigmentation (circumoral; 95% of patients), hands (70%) and feet (60%) and gastrointestinal polyps. It has an autosomal dominant inheritance. The gene *STK11* (also known as *LKB1*) responsible for Peutz-Jeghers codes for a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of the condition. The polyps, which are hamartomas, can occur anywhere in the GI tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception (50% of patients).

Treatment is by endoscopic polypectomy. Balloon enteroscopy may be necessary to reach all the small bowel polyps. Bowel resection should be avoided if possible, but may be necessary in patients presenting with gangrenous bowel due to intussusception. Follow-up is with yearly panendoscopy. There is an increased incidence of GI cancers. Non-GI cancers also occur with increased frequency, so yearly screening for uterine, ovarian and cervical cancer should start in the teens, and breast and testicular screening by the age of 20.

Other tumours

Adenomas, lipomas and stromal tumours (see p. 253) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis (FAP) duodenal adenomas form in one-third of patients and may progress to adenocarcinoma. This is the commonest cause of death in FAP patients who have been treated by prophylactic colectomy.

INFLAMMATORY BOWEL DISEASE (IBD)

Two major forms of inflammatory bowel disease are recognized:

- Crohn's disease (CD), which can affect any part of the GI tract
- Ulcerative colitis (UC), which affects only the colon.

There is a degree of overlap between these two conditions in their clinical features, histological and radiological abnormalities; in 10% of cases of IBD causing colitis a definitive diagnosis of either UC or CD is not possible and the diagnosis is termed colitis of undetermined type and etiology (CUTE). It is clinically useful to distinguish between these two conditions because of differences in their management, although in reality they may represent two aspects of the same disease.

Another form of colitis related to microscopic inflammation is termed microscopic colitis; this is subdivided into lymphocytic and collagenous (see p. 281). The distinction between this and IBD is the absence of macroscopic evidence of inflammation.

Epidemiology

- The incidence of CD varies from country to country but is approximately 4–10 per 100 000 annually, with a prevalence of 25–100/100 000.
- The incidence of UC is stable at 6–15/100 000 annually, with a prevalence of 80–150/100 000.

Although both conditions have a worldwide distribution, the highest incidence rates and prevalence have been reported from northern Europe, the UK and North America. Both race and ethnic origin affect the incidence and prevalence of CD and UC. Thus, in North America, prevalence rates of CD are lower in Hispanic and Asian people (4.1, 5.6/100 000, respectively) compared with white individuals (43.6/100 000). Jewish people are more prone to inflammatory bowel disease than any other ethnic group. Prevalence rates also change after migration, thus there is an increasing incidence of Crohn's disease in the UK-born children of migrants from South-east Asia.

Approximately 25% patients are diagnosed before their 18th birthday and there is increasing evidence that disease commencing in youth is more extensive and more aggressive than that occurring in older patients.

Aetiopathogenesis

Although the aetiology of IBD is unknown, it is increasingly clear that IBD represents the interaction between several co-factors: genetic susceptibility, the environment, the intestinal microbiota and host immune response (Fig. 6.30a).

Genetic factors

CD and UC are complex polygenic diseases and having a positive family history is the largest independent risk factor

for development of IBD. Up to one in five patients with CD and one in six patients with UC will have a 1st-degree relative with the disease. The monozygotic and dizygotic twin concordance rates for CD are 20–50% and 10%, respectively.

Genome Wide Association Studies have identified multiple susceptibility loci and many of the underlying risk variants have been identified. The major genetic factors are the NOD 2 gene (nucleotide oligomerization domain 2), the autophagy genes and the Th17 pathway (interleukin 23-type 17 helper T cells). The NOD 2 protein on chromosome 16 is an intracellular sensor of bacterial peptidoglycan, present in bacterial cell walls (see below). NOD 2 is expressed in epithelial cells, macrophages, endothelial cells. Individuals who are homozygote or compound heterozygote for one of several mutations in the NOD 2 gene have a significant increased risk of developing ileal Crohn's disease. Likewise mutations in the autophagy genes ATG16L1 and IRGM (immunity-related GTP-ase M-protein) and IL-23 receptor gene increase CD risk, and mutations in genes associated with the mucosal barrier increase UC risk. However, the presence of IBD associated genes in many unaffected individuals and the failure of the approximately 71 genetic susceptibility loci identified thus far to explain more than around one-fifth of the genetic risk of CD highlights the complexity of the genetic basis of IBD.

Apart from susceptibility, HLA genes on chromosome 6 also appear to have a role in modifying the disease. The *DRB*0103* allele, which is uncommon, is linked to a particularly aggressive course of UC and the need for surgery, as well as with colonic CD. *DRB*0103* and *MICA*010* are associated with perianal disease and *DRB*0701* with ileal CD. For the extraintestinal disease complications and HLA links, see p. 275.

Environmental and other factors

- **Smoking:** Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD and increase the risk of disease recurrence after surgery. By contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment in one small clinical trial.
- **Non-steroidal anti-inflammatory drugs:** NSAID ingestion is associated with both the onset of IBD and flares of disease in patients with an established diagnosis.
- **Hygiene:** Good domestic hygiene has been shown to be a risk factor for CD but not for UC. Poor and large families living in crowded conditions have a lower risk of developing CD. A 'clean' environment may not expose the intestinal immune system to pathogenic or non-pathogenic microorganisms such as helminths which seems to alter the balance between effector and regulatory immune responses.
- **Nutritional factors:** Many foods and food components have been suggested to play a role in the aetiopathogenesis of IBD (e.g. high sugar and fat intake) but unfortunately the results of numerous studies designed to define risk have been equivocal. However, breast-feeding may provide protection against inflammatory bowel disease developing in offspring.
- **Psychological factors** such as chronic stress and depression seem to increase relapses in patients with quiescent disease.

Figure 6.30 Inflammatory bowel disease. (a) Schematic diagram showing the aetiopathogenesis. **(b)** Cellular intestinal processes. Bacterial ligands attach to the epithelium and antigen presenting cells via Toll-like receptors and the NOD protein. This triggers the release of various cytokines. (Modified from Abraham C, Cho JH. Inflammatory bowel disease. *N Engl J Med* 2009; 361:2066–2078.)

■ **Appendectomy** appears 'protective' for the development of UC, particularly if performed for appendicitis or for mesenteric lymphadenitis before the age of 20. It also influences the clinical course of UC, with a lower incidence of colectomy and need for immunosuppressive therapy. By contrast, appendectomy may increase the risk of development of CD.

The intestinal microbiota

The gut is colonized by 10 times more bacterial organisms than there are host cells, there being 300–400 distinct bacterial species. The intestinal microbiota play a crucial role in perpetuating intestinal inflammation, both in animal models of disease and patients with IBD. Thus, in transgenic murine models of IBD, animals kept under germ-free conditions do not develop inflammation until bacteria are introduced.

FURTHER READING

Kaser A, Zeissig S, Blumberg RS. Inflammatory bowel disease. *Annu Rev Immunol* 2010; 28:573–621.

Likewise, the number of mucosal adherent bacteria is increased in patients with Crohn's disease compared to healthy subjects and diversion of the bacterial component of the faecal stream induces clinical remission. However, there is also evidence for an immunoregulatory role for the commensal microbiota, which protect against intestinal inflammation and upregulate epithelial defence mechanisms in animal models of colitis.

- **Intestinal dysbiosis.** There is an alteration in the bacterial flora in patients with Crohn's disease. Although results vary due to differences in both the patient groups studied and the microbiological method utilized, higher concentrations of *Bacteroides* and *Escherichia coli* and lower concentrations of bifidobacteria and *F. prausnitzii* have been reported in faecal and mucosal samples from patients with CD compared to healthy controls. Lower concentrations of *F. prausnitzii* have been found in patients with active compared with quiescent disease, and low levels of this organism in CD resection specimens predict subsequent endoscopic disease recurrence.
- **Specific pathogenic organisms.** It has been shown that there is increased *E. coli* adherence to the ileal-epithelial cells in CD with evidence of invasion into the mucosa. This occurs via *E. coli*'s type 1 pili to a protein called carcinoma embryonic antigen-related cell adhesion molecule 6 (CEACAM 6). Many authors have also suggested a link between Crohn's disease and *Mycobacterium paratuberculosis*, although recent PCR based studies have failed to confirm this and a therapeutic trial of anti *Mycobacterium tuberculosis* (MTB) therapy was not effective.
- **Bacterial antigens.** Bacteria exert their influence by the interaction of ligands such as peptidoglycan-polysaccharides (PG-PS) and lipopolysaccharides (LPS) interacting with host pattern recognition receptors such as the Toll-like receptor family (cell surface) and the NOD family (intracellular).
- **Defective chemical barrier or intestinal defensins** (see p. 262). Evidence suggests a decrease in human α defensin-1 (HD-1) in both CD and UC and lack of induction of HD-2 and HD-3, HD-5 in CD.
- **Impaired mucosal barrier function** may explain the presence of unusual and potentially pathogenic bacteria, e.g. *Mycobacterium paratuberculosis* (MAP), *Listeria* and mucosal adherent *E. coli*. However, their presence does not necessarily imply causation of the disease.
- **Butyrate.** Sulphate-producing bacteria increase luminal levels of hydrogen sulphide (H_2S), which leads to a reduction of butyrate oxidation in colonic mucosa, producing an energy-deficient state and leading to mucosal inflammation. H_2S and methanethiol may produce the malodorous flatus that some patients complain of prior to a flare-up.

The intestinal immune system

IBD occurs when the mucosal immune system exerts an inappropriate response to luminal antigens, such as bacteria, which may enter the mucosa via a leaky epithelium (Fig. 6.30b). Bacterial ligands interact with the innate and acquired mucosal immune system via Toll-like receptors expressed on both epithelial and antigen-presenting cells. Recent research has highlighted deficiencies in the clearance of invading bacteria by aspects of the innate immune system such as

neutrophils, which may allow inappropriate activation of the acquired immune system. In keeping with the genetic susceptibility loci identified, these findings highlight a deficiency in a component of the inflammasome (an intracellular danger sensor of the innate immune system which can trigger caspase-1-dependent processing of inflammatory mediators, such as IL-1 β and IL-18) in patients with IBD. In addition, specific bacterial species have distinct immunological effects mediated by dendritic cells (DC) which sample bacteria from the intestinal lumen and direct the subsequent functional differentiation of naive T cells into effector or regulatory populations. IBD is associated with an imbalance in the relative numbers of intestinal homing effector (Th1 and Th17) and regulatory T cell populations which disturb the normal tolerance to the luminal antigenic load.

The pro-inflammatory cytokines released by these activated effector T cells stimulate macrophages to secrete pro-inflammatory cytokines such as tumour necrosis factor α (TNF- α), IL-1 and IL-6 in large quantities. These mechanisms result in increased adhesion molecule expression on the intestinal vascular endothelium, which facilitates the recruitment of leucocytes from the circulation and the release of chemokines all of which lead to tissue damage and also attract more inflammatory cells in a vicious circle.

Pathology

- Crohn's disease is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease) (Fig. 6.31). The disease can involve one small area of the gut such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis) sometimes without macroscopic small bowel involvement.
- Ulcerative colitis can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (extensive colitis) (Fig. 6.32). In a few of these patients there is also inflammation of the distal terminal ileum (backwash ileitis).

Macroscopic changes

In Crohn's disease, the involved bowel is usually thickened and often is narrowed. Deep ulcers and fissures in the

mucosa produce a cobblestone appearance. Fistulae and abscesses may be seen which reflect penetrating disease. An early feature is aphthoid ulceration, usually seen at colonoscopy; later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.

In ulcerative colitis, the mucosa looks reddened, inflamed and bleeds easily (friability). In severe disease there is extensive ulceration with the adjacent mucosa appearing as inflammatory (pseudo) polyps.

In fulminant colonic disease of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilatation occurs. On healing, the mucosa can return to normal, although there is usually some residual scarring.

Microscopic changes

In Crohn's disease, the inflammation extends through all layers (transmural) of the bowel, whereas in UC a superficial inflammation is seen. In CD, there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50–60% of patients granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans' giant cells.

In ulcerative colitis, the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

The differentiation between these two diseases can usually be made not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (Table 6.10).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase, and such patients are considered to have a Colitis of Undetermined Type and Aetiology (CUTE). Serological testing for anti-neutrophil cytoplasmic antibodies (ANCA) in UC and anti-*Saccharomyces cerevisiae* antibodies (ASCA) (CD) may be of value in differentiating the two conditions (see p. 279) although an exact diagnosis can sometimes only be made after examining a surgical colectomy specimen. Occasionally, examination of the colectomy specimen still does not lead to a diagnosis of CD or UC and the patient is labelled as having indeterminate colitis.

Table 6.10 Histological differences between Crohn's disease and ulcerative colitis

	Crohn's disease	Ulcerative colitis
Inflammation	Deep (transmural) patchy	Mucosal continuous
Granulomas	++	Rare
Goblet cells	Present	Depleted
Crypt abscesses	+	++

Table 6.11 Extragastrintestinal manifestations of inflammatory bowel disease

Eyes	Skin
Uveitis	Erythema nodosum
Episcleritis, conjunctivitis	Pyoderma gangrenosum
Joints	Liver and biliary tree
Type I (pauciarticular) arthropathy	Sclerosing cholangitis
Type II (polyarticular) arthropathy	Fatty liver
Arthralgia	Chronic hepatitis
Ankylosing spondylitis	Cirrhosis
Inflammatory back pain	Gallstones
	Nephrolithiasis
	Venous thrombosis

Extragastrintestinal manifestations

These occur with both diseases (Table 6.11). Joint complications are most common, and the peripheral arthropathies are classified as type 1 (pauciarticular) and type 2 (polyarticular).

Type 1 attacks are acute, self-limiting (<10 weeks) and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity.

Type 2 arthropathy lasts longer (months to years), is independent of IBD activity and usually associated with uveitis.

The incidence of joint and other extragastrintestinal manifestations is shown in Table 6.11. There is an association of HLA DRB1*0103 with pauciarticular large joint arthritis in UC and CD and small joint symmetrical arthritis with HLAB44. HLA B27 is associated with sacroiliitis.

Differential diagnosis

Alternative causes of diarrhoea should be excluded (see Table 6.21) and stool cultures (including *Clostridium difficile* toxin assay) must always be performed. Stool microscopy for parasitic diseases such as amoebiasis should be performed in patients with a relevant travel history. Crohn's disease should be considered in all patients with evidence of vitamin malabsorption, e.g. megaloblastic anaemia, or malnourishment, as well as in children with reduced growth velocity. Ileocolonic tuberculosis (see p. 269) is common in developing countries, e.g. India, which makes a diagnosis of CD difficult. Microscopy and culture for TB of any available tissue is essential in these countries. A therapeutic trial of antituberculosis therapy may be required. Lymphomas can occasionally involve the ileum and caecum although are rare in the patient population at risk from inflammatory bowel disease.

Crohn's disease

Clinical features

The major symptoms are diarrhoea, abdominal pain and weight loss. Constitutional symptoms of malaise, lethargy,

Crohn's disease. Colonoscopic appearances of **(a)** aphthoid ulcers typical of Crohn's disease, **(b)** deep serpiginous ulceration in colonic Crohn's disease.

anorexia, nausea, vomiting and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Despite the recurrent nature of this condition, some patients have an almost normal lifestyle. However, patients with extensive disease have frequent recurrences and progress from inflammatory to stricturing and penetrating disease. Approximately 50% of patients will require an intestinal resection within 5 years of diagnosis.

The clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. The abdominal pain can be colicky, suggesting obstruction, but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea is present in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from UC. Steatorrhoea can be present in small bowel disease. Diarrhoea can also be due to bile acid malabsorption occurring as a consequence of ileal resection or ileal disease.

Crohn's disease can also present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous reddened terminal ileum is found. Other causes of an acute ileitis include infections such as *Yersinia* and tuberculosis.

Crohn's disease is complicated by anal and perianal disease and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms (Table 6.12). Enteric fistulae, e.g. to bladder or vagina or abdominal wall, occur in 20–40% of cases.

Examination

Physical signs are few, apart from loss of weight and signs of malnutrition. Aphthous ulceration of the mouth is often seen. Abdominal examination may be normal although tenderness and/or a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess which may also cause psoas muscle irritation. The anus should always be examined to look for oedematous anal tags, fissures or perianal abscesses.

The presence of extragastrointestinal features of inflammatory bowel disease should be assessed (see Table 6.11).

Investigations

Blood tests

- **Anaemia** is common and may be the normocytic, normochromic anaemia of chronic disease. However, deficiency of iron and/or folate also occurs. Despite terminal ileal involvement in CD, megaloblastic anaemia due to B₁₂ deficiency is unusual, although serum B₁₂ levels can be below the normal range.
- **Raised ESR and C-reactive protein (CRP)** and a raised white cell count and platelet count.
- **Hypoalbuminaemia** is present in severe disease or as part of an acute phase response to inflammation associated with a raised CRP.

Table 6.12 Anal and perianal complications of Crohn's disease

Fissure in ano (multiple and indolent)
Haemorrhoids
Skin tags
Perianal abscess
Ischiorectal abscess
Fistula in ano (may be multiple)
Anorectal fistulae

- **Liver biochemistry** may be abnormal.
- **Blood cultures** are required if septicaemia is suspected.
- **Serological tests.** pANCA is negative (p. 279).

Stool tests

Stool cultures including *Clostridium difficile* toxin assay should always be performed if diarrhoea is present. Microscopy for parasites is essential in patients with a relevant travel history.

Faecal calprotectin and lactoferrin are raised in active colonic disease.

Endoscopy and radiological imaging

Colonoscopy is performed if colonic involvement is suspected except in patients presenting with severe disease (in whom a limited unprepared sigmoidoscopy should be performed). The findings vary from mild patchy superficial (aphthoid) ulceration to more widespread larger and deeper ulcers producing a cobblestone appearance.

Upper GI endoscopy is required to exclude oesophageal and gastroduodenal disease in patients with relevant symptoms and is increasingly being performed in all patients at diagnosis to accurately define the extent of disease as a guide to prognosis.

Small bowel imaging is mandatory in patients with suspected Crohn's disease. The technique used will depend on availability and local expertise. Techniques include *barium follow-through*, *CT scan* with oral contrast, small bowel ultrasound or MRI enteroclysis. The findings include an asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or stricturing. Although commonly confined to the terminal ileum (Fig. 6.33), other areas of the small bowel can be involved and skip lesions with normal bowel are seen between affected sites. Axial imaging allows diagnosis of extraintestinal sepsis in patients presenting acutely and is therefore preferred in this situation.

Perianal MRI or endoanal ultrasound are used to evaluate perianal disease.

Capsule endoscopy is used in Crohn's disease patients who have a normal radiological examination.

Radionuclide scans with indium- or technetium-labelled leucocytes are used in some centres to identify small intestinal and colonic disease inflammation and to localize extraintestinal abscesses.

Disease activity

This can be assessed using simple parameters such as Hb, white cell count, inflammatory markers (raised ESR, CRP and platelet count) and serum albumin. Formal clinical activity indices (e.g. CD Activity Index) are used in research studies. Faecal calprotectin or lactoferrin have the potential to be a simple cheap non-invasive marker of disease activity in IBD and are of value in predicting response to and failure of treatment.

Medical management of Crohn's disease (Box 6.6)

General considerations

The aim of management is to induce and then maintain clinical remission and achieve mucosal healing to prevent complications. Alternative causes for symptoms such as extraintestinal sepsis, stricture formation, functional GI disease or bile salt malabsorption must be excluded before commencing immunosuppressive therapy. Patients with mild symptoms and no evidence of extensive disease may require only symptomatic treatment. Cigarette smoking should be stopped. In the absence of significant colonic

Box 6.6 Options for medical treatment of Crohn's disease

Induction of remission

- Oral or i.v. glucocorticosteroids
- Enteral nutrition
- Anti-TNF antibodies

Maintenance of remission

- Azathioprine, 6MP, methotrexate, mycophenolate mofetil
- Anti-TNF antibodies

Perianal disease

- Ciprofloxacin and metronidazole
- Azathioprine
- Anti-TNF antibodies

disease diarrhoea can be controlled with loperamide, codeine phosphate or co-phenotrope. Diarrhoea in longstanding inactive disease or after ileal resection may be due to bile acid malabsorption (see p. 293) and should be treated with bile salt sequestrants. Anaemia, if due to vitamin B₁₂, folic acid or iron deficiency, should be treated with the appropriate haematinics. A few patients are intolerant of oral iron and should receive an intravenous iron infusion. Most patients can be treated as outpatients, although severe attacks may require admission and prophylaxis for thromboembolism should be given.

Induction of remission

Glucocorticosteroids are commonly used to induce remission in moderate and severe attacks of CD (oral prednisolone

30–60 mg/day). Mild to moderate ileocaecal disease should be treated with controlled release corticosteroids such as budesonide. Budesonide has high topical potency and because of its extensive hepatic inactivation has low systemic availability, which induces less suppression of endogenous cortisol and reduces frequency and intensity of steroid side-effects. Overall remission/response rates vary from 60% to 90% depending on type, site and extent of disease. Steroids should be avoided in patients with penetrating intestinal or perianal sepsis.

Aminosalicylates have been used but there is little evidence to support their efficacy in CD.

Antibiotics (ciprofloxacin and metronidazole) are used for treating secondary complications of CD (e.g. abscess and perianal disease). Rifaximin has been shown to induce remission in moderately active Crohn's disease, in a clinical trial.

Exclusive enteral nutrition is the traditional treatment for moderate to severe attacks of Crohn's disease in paediatric practice, but is underutilized in adults due to issues with compliance to the diet. If enteral diets with low fat (1.3% of total calories) and low linoleic acid content are administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

Refractory disease. Patients with symptoms that do not respond to conventional therapy should be re-assessed to exclude an alternative diagnosis such as a stricture or penetrating abscess. In patients with disease limited to the

Van Assche G, Vermeire S, Rutgeerts P. The potential for disease modification in Crohn's disease. *Nat Rev Gastroenterol Hepatol* 2010; 7:79–85.

terminal ileum, surgical resection is appropriate. In patients with more extensive disease, remission should be induced with an anti-TNF agent either as monotherapy or preferably in combination with an immunosuppressive such as azathioprine (see below).

Maintenance of remission

Patients with good prognosis disease (older age at diagnosis, no perianal disease, limited ulceration at index investigations, non-smoker) may not require maintenance therapy. Patients with poor prognosis disease (young age at diagnosis, extensive small bowel disease, deep colonic ulceration, smoker) or those who flare after withdrawing induction therapy require long-term immunosuppression. The goal of maintenance therapy is to prevent disease progression to a stricturing or penetrating phenotype as well as to reduce the need for corticosteroids which are associated with a high burden of side-effects. Therapies that induce mucosal healing result in better outcomes. All maintenance therapies require careful monitoring to ensure optimal disease control and prevent side-effects.

Conventional maintenance therapies include *azathioprine* (AZA, 2.5 mg/kg per day), *mercaptopurine* (MP, 1.5 mg/kg per day), *methotrexate* (25 mg once a week until remission, then reduced to 15 mg per week) (Box 6.6). Long-term treatment with these drugs is necessary as the rate of relapse on discontinuation is high. Patient education regarding side-effects and appropriate monitoring for complications is essential and may increase adherence. Careful monitoring is required as leucopenia can occur. The key enzyme involved in AZA and MP metabolism is thiopurine methyl transferase (TPMT). This enzyme has a significant genetic variation and deficiencies can result in high circulating levels of thioguanine nucleotides with increased risk of bone marrow depression. Assays of TPMT activity are now available and should be performed before treatment. TPMT deficiency is not the only cause of bone marrow depression so 3-monthly blood counts should be performed on all patients.

Anti-TNF agents have clear evidence of benefit in the maintenance of remission in patients with Crohn's disease. They are indicated in patients with disease refractory to conventional immunosuppressive therapy. Early use of anti-TNF therapy is indicated in selected patients with poor prognosis disease (see above). They are also used to treat complex perianal/rectal disease once sepsis has been drained. Available anti-TNF agents include *infliximab* (a chimeric anti-TNF- α IgG1 monoclonal antibody), *adalimumab* (a fully humanized anti-TNF IgG1 monoclonal antibody) and *certolizumab pegol* (a PEGylated Fab' fragment of a humanized anti-TNF antibody). They neutralize soluble TNF- α , bind to membrane bound TNF- α and induce immune cell apoptosis, although the exact mechanism of action is not defined. In clinical trials they have been shown to exert a steroid sparing effect and result in complete mucosal healing in up to one-third of patients in the long term. This results in reduced need for hospital admission and surgery. They should always be used for a defined maintenance period as they are less effective and induce anti-drug antibodies if used episodically. In patients who are naive to azathioprine, combination therapy increases efficacy and reduces immunogenicity. Their use should be limited to clinicians experienced in the management of Crohn's disease as they are associated with significant complications including opportunistic infections (including tuberculosis), demyelination and malignancy such as lymphoma.

Novel biological therapies for the treatment of Crohn's disease that are currently in clinical trials include the anti

$\alpha 4\beta 7$ integrin therapy vedolizumab, which acts to reduce leucocyte recruitment to the inflamed intestine. Therapies that target the IL-12/IL-23 pathway such as ustekinumab are being used in the USA.

Surgical management of Crohn's disease

Approximately 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable without prophylactic maintenance therapy. The indications for surgery are:

- Failure of medical therapy, with acute or chronic symptoms producing ill-health
- Complications (e.g. toxic dilatation, obstruction, perforation, abscesses, enterocutaneous fistula)
- Failure to grow in children despite medical treatment.
- Presence of perianal sepsis: an examination under anaesthetic is performed, the sepsis is drained and a seton is inserted to ensure ongoing drainage.

In patients with small bowel disease, some strictures can be widened (stricturoplasty), whereas others require resection and anastomosis.

When colonic CD involves the entire colon and the rectum is spared or minimally involved, a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60–70% in the ileum, rectum or both is to be expected; however, two-thirds of these patients retain a functional rectum for 10 years. If the whole colon and rectum are involved, a panproctocolectomy with an end ileostomy is the standard operation. In this operation, the colon and rectum are removed and the ileum is brought out through an opening in the right iliac fossa and attached to the skin. The patient wears an ileostomy bag, which is stuck on to the skin over the ileostomy spout. CD patients are not suitable for a pouch operation (see p. 280) as recurrence in the pouch is high.

Problems associated with ileostomies include:

- Mechanical problems
- Dehydration, particularly if there is a short length of small bowel remaining
- Psychosexual problems
- Erectile dysfunction in men and reduced fecundity in women (due to prior pelvic surgery)
- Recurrence of CD.

Ulcerative colitis

Clinical features

The major symptom in UC is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal discomfort. General features include malaise, lethargy and anorexia with weight loss, although these features are less than with CD. Aphthous ulceration in the mouth may be seen. The disease can be mild, moderate or severe (Table 6.13), and in most patients runs a course of remissions and exacerbations. Of the patients, 10% have persistent chronic symptoms, while some patients may have only a single attack. Disease extent is defined as limited to the rectum (proctitis), left-sided or extensive (see Fig. 6.32).

Proctitis is characterized by the frequent passage of blood and mucus, urgency and tenesmus. There are normally few constitutional symptoms and the stool when passed, may be solid. Patients are nevertheless greatly inconvenienced by the frequency of defecation.

Table 6.13 Definition and management of a severe attack of ulcerative colitis

Definition	
Stool frequency	>6 stools/day with blood +++
Fever	>37.5°C
Tachycardia	>90/min
ESR	>30 mm/h
Anaemia	<100 g/L haemoglobin
Albumin	<30 g/L
Management	
Admit to hospital	
Assess i.v. fluids	
Give prophylactic anticoagulation	
Monitor daily:	
stool frequency	
abdominal X-ray	
FBC, CRP	
albumin	

**Figure 6.34** Plain abdominal X-ray showing toxic dilatation. The arrows indicate mucosal islands.

In an acute attack of left-sided or extensive UC, patients have bloody diarrhoea, passing up to 10–20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Patients with a severe flare of colitis (Table 6.13) require urgent admission for intensive therapy.

Toxic megacolon is a serious complication associated with severe colitis. The plain abdominal X-ray shows a dilated thin-walled colon with a diameter of >6 cm; it is gas filled and contains mucosal islands (Fig. 6.34). It is a particularly dangerous stage of advanced disease with impending perforation and a high mortality (15–25%). Urgent surgery is required in all patients in whom toxic dilatation has not resolved within 48 hours with intensive therapy as above. The differential diagnosis includes an infectious colitis, e.g. *C. difficile* and CMV.

Examination

In general, there are no specific signs in UC. The abdomen may be slightly distended or tender to palpation. Tachycardia and pyrexia are signs of severe colitis and mandate admission. The anus is usually normal. Rectal examination will show the presence of blood. Rigid sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa.

Very occasionally, rectal sparing occurs, with normal sigmoidoscopy.

Investigations

Blood tests

- In moderate to severe attacks, iron deficiency anaemia is commonly present and the white cell and platelet counts are raised.
- The ESR and CRP are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.
- pANCA may be positive. This is contrary to CD, where pANCA is usually negative (see p. 276).

Stool cultures and *Clostridium difficile* toxin

These should always be performed to exclude infective causes of colitis. Stool microscopy to exclude amoebiasis is mandated in patients with a relevant travel history. Faecal calprotectin/lactoferrin will be elevated.

Colonoscopy

Endoscopy with mucosal biopsy is the 'gold standard' investigation for the diagnosis of UC. Colonoscopy also allows assessment of disease activity and extent. In patients with long-term colitis, chromoendoscopy is used to diagnose dysplasia. Full colonoscopy should not be performed in severe attacks of disease for fear of perforation – a limited unprepared sigmoidoscopy should be used to confirm diagnosis.

Imaging

A plain abdominal X-ray is essential in patients with severe attacks to exclude colonic dilatation. However, the extent of disease is not reliably assessed using this investigation. Other imaging investigations are rarely used in the assessment of patients with UC as endoscopy is preferred. However, inflammation of the colonic wall is detected on ultrasound as is the presence of free fluid within the abdominal cavity. In patients with severe colitis in whom full colonoscopy is contraindicated, disease extent should be assessed by technetium-labelled white cell scan.

Medical management of ulcerative colitis (UC)

Wherever possible, patients with IBD should be managed in patient-focused inflammatory bowel disease clinics with access to a full multidisciplinary team. The mainstay of treatment for mild and moderate disease of any extent is an aminosalicilate which acts topically in the colonic lumen. The active moiety of these drugs is 5-aminosalicylic acid (5-ASA), which is absorbed in the small intestine. Therefore, the various aminosalicilate preparations are designed to deliver the active 5-ASA to the colon. This is achieved by binding of 5-ASA with an azo bond to sulfapyridine (sulfasalazine), 4-aminobenzoyl-β-alanine (balsalazide) or to 5-ASA itself (olsalazine), coating with a pH-sensitive polymer (Asacol), packaging of 5-ASA in microspheres (Pentasa), or a combination of these (Mezavant®). The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon. The pH-dependent forms are designed to release 5-ASA in the proximal colon. Luminal pH profiles in patients with inflammatory bowel disease are abnormal and in some patients capsules of 5-ASA coated with pH-sensitive polymer may pass through into the faeces intact. 5-ASA is released from microspheres throughout the small intestine and colon.

The mode of action of 5-ASA in inflammatory bowel disease is unknown although it may involve the intracellular

Van Assche G, Vermeire S, Rutgeerts P. Management of acute severe ulcerative colitis. *Gut* 2011; 60:130–133.

PPAR- γ signalling pathway. The aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease and maintaining remission in all forms of disease. There is also evidence that they are chemopreventative for UC-associated colorectal cancer.

Proctitis

Rectal 5-ASA suppositories are the first-line treatment. Topical steroids are less effective than 5-ASA preparations. Oral 5-ASA can be added to increase remission rates. Some cases of proctitis can be 'resistant' to 5-ASA treatment and require oral prednisolone.

Left-sided colitis

Topical 5-ASA enemas are the first line treatment. The addition of an oral 5-ASA will increase remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Extensive colitis

Patients with mild to moderate symptoms can be treated with an oral 5-ASA at an adequate dose. The additional of a 5-ASA enema increases remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Severe colitis of any extent

Patients with severe colitis (Table 6.13) or those who do not respond to oral prednisolone should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly with s.c. low molecular weight heparin to prevent thromboembolism. Investigations to confirm the diagnosis and exclude enteric infection (see above) should be performed and full supportive therapy administered (i.v. fluids, nutritional support via the enteral route if required). The incidence of concomitant *C. difficile* infection in patients admitted for severe colitis is increasing. This is associated with a significant increase in morbidity and must be excluded. The clinical status of patients should be monitored daily (fever, tachycardia, stool frequency) and daily FBC, CRP, urea and electrolytes should be performed. Repeat abdominal X-rays are required if patients are not improving. Success or failure of medical treatment of a severe attack of UC must be judged by an experienced gastroenterologist and colorectal surgeon. If patients have not responded to i.v. steroids within 3 days either salvage medical therapy or surgery is required. If patients respond to i.v. steroids they should be switched to oral prednisolone which can be weaned over 8–10 weeks. All patients who have been admitted for severe colitis should commence long-term maintenance therapy with a thiopurine (azathioprine/mercaptopurine).

Salvage therapy

Salvage therapy to avoid colectomy is required for patients with a CRP >45 mg/L or more than eight bowel motions after 3 days of i.v. hydrocortisone. Continuing steroid therapy alone in this situation will delay the inevitable colectomy and increase mortality. Salvage medical therapies with clear evidence of benefit in controlled clinical trials are i.v. ciclosporin 2 mg/kg per day as a continuous infusion or infliximab 5 mg/kg as an infusion. These should only be used by experienced gastroenterologists as part of a multidisciplinary team with colorectal surgeons. Steroids should be weaned rapidly once salvage therapy has commenced to reduce morbidity. Patients who respond should be treated with oral ciclosporin or further infliximab infusions respectively, while being commenced on maintenance thiopurine therapy.

Box 6.7 Indications for surgery in ulcerative colitis

Fulminant acute attack

- Failure of medical treatment
- Toxic dilatation
- Haemorrhage
- Imminent perforation

Chronic disease

- Incomplete response to medical treatment/steroid dependant
- Dysplasia on surveillance colonoscopy

Figure 6.35 An ileo-anal pouch for ulcerative colitis.

Surgical management of ulcerative colitis

While the treatment of UC remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative and eliminates the long-term risk of cancer. The main indication for surgery is for a severe attack which fails to respond to medical therapy. Other indications are listed in Box 6.7. In expert centres laparoscopic surgery is often used to improve postoperative pain, recovery time and cosmesis.

In acute disease, subtotal colectomy with end ileostomy and preservation of the rectum is the operation of choice. At a later date, a number of surgical options are available and are best carried out in a specialist colorectal centre. These include proctectomy with a permanent ileostomy, or to avoid a permanent ileostomy an ileo-anal anastomosis can be formed (Fig. 6.35). The ileoanal pouch is anastomosed to the anus at the dentate line following excision of the remaining rectum. A third of patients, however, will experience 'pouchitis', in which there is inflammation of the pouch mucosa with clinical symptoms of diarrhoea, bleeding, fever and at times exacerbation of extracolonic manifestations (Fig. 6.36). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis and is also raised in patients with a positive ANCA and backwash ileitis prior to colectomy. Two-thirds of pouchitis cases will recur either as acute relapsing or chronic unremitting forms. The mainstay of treatment is antibiotics (metronidazole \pm ciprofloxacin). Treatment is not always satisfactory and steroids may be required. The probiotic VSL#3 has been shown to be effective to prevent the onset of pouchitis and to maintain remission in pouchitis patients with antibiotic induced mucosal healing (Box 6.8).

Figure 6.36 Pouchitis. Fiberoptic sigmoidoscopic appearances. (a) Mild changes. (b) Severe haemorrhagic ulceration.

Box 6.8 Probiotic use in inflammatory bowel disease

Probiotics are live microorganisms which when ingested can modify the composition of enteric microflora. Commonly used probiotics are lactobacilli, bifidobacteria, non-pathogenic *E. coli*.

Rationale for use

- Evidence of dysbiosis (dysbacteriosis) in patients with IBD
- Evidence that specific bacteria are pro-inflammatory and others immunoregulatory
- *In vitro* isolates of normal bacteria inhibit growth of pathogenic bacteria
- Regulatory signals between bacterial flora and intestinal epithelial cells maintain mucosal integrity.

Use

- Pouchitis (see p. 280) – VSL#3 can prevent onset and maintain a remission
- *E. coli* Nissle 1914 may be useful in maintaining remissions in ulcerative colitis.

Course and prognosis

One-third of patients with distal inflammatory proctitis due to UC will develop more proximal disease, with 5–10% developing total colitis. One-third of patients with UC will have a single attack and the others will have a relapsing course. One-third of patients with UC will undergo colectomy within 20 years of diagnosis.

Cancer in inflammatory bowel disease

Patients with UC and extensive Crohn's colitis have an increased incidence of developing dysplasia and subsequent colon cancer. The risk of dysplasia is related to the extent and duration of disease as well as the presence of untreated mucosal inflammation. A family history of colorectal cancer and the presence of primary sclerosing cholangitis also increase the risk. Appropriate colonoscopic screening strategies according to guidelines are used by many, although evidence for overall benefit is lacking. Patients with CD of the small intestine have a small increase in the incidence of small bowel carcinoma.

Pregnancy and inflammatory bowel disease

Women with inactive IBD have normal fertility. Fertility, however, may be reduced in those with active disease, and patients with active disease are twice more likely to suffer spontaneous abortion than those with inactive disease.

The rate of relapse of UC in pregnant patients is similar to non-pregnant patients and is often due to inappropriate

discontinuation of maintenance therapy. The risk of a flare-up in the puerperal period is enhanced in patients who have a flare-up in the 1st trimester. Patients with CD, like those with UC, do not have an increased risk of flare-up during pregnancy. Relapse (if it does occur) is, however, more likely during the 1st trimester.

Aminosalicylates, steroids and azathioprine are safe at the time of conception and during pregnancy. Methotrexate is teratogenic and is contraindicated. The sulfapyridine moiety of sulfasalazine impairs spermatogenesis, so the partners of women trying to conceive should be treated with an alternative aminosalicylate. There is no good evidence that male patients with IBD should stop either AZA or 6MP. Infliximab and adalimumab cross the placenta in the 3rd trimester of pregnancy; patients who become pregnant while on an anti-TNF agent should be managed on a case-by-case basis by an expert in this scenario.

Mortality in inflammatory bowel disease

Population-based studies demonstrate mortality in UC is similar to that in the general population. The two exceptions are patients with severe colitis who have a slightly higher mortality in the first year after diagnosis and patients aged over 60 at the time of diagnosis. Although currently it is unclear whether there is a slightly higher overall mortality in patients with CD, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a relatively higher mortality.

Microscopic colitis

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- **Microscopic ulcerative colitis.** There is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture, and goblet cell depletion with or without crypt abscesses. Treatment is as for UC; many patients respond to treatment with aminosalicylates alone.
- **Microscopic lymphocytic colitis.** There is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium and increased lamina propria mononuclear cells.
- **Microscopic collagenous colitis.** There is a thickened subepithelial collagen layer ($>10\ \mu\text{m}$) adjacent to the basal membrane with increased infiltration of the lamina propria with lymphocytes and plasma cells and surface epithelial cell damage. It is predominantly a disorder of

middle-aged or elderly females, and is associated with a variety of autoimmune disorders (arthritis, thyroid disease, limited cutaneous scleroderma (see p. 539) and primary biliary cirrhosis). The incidence of both microscopic lymphocytic and collagenous colitis is increased in patients with coeliac disease and this must be excluded in these patients. Treatment of microscopic and collagenous colitis is usually with budesonide. There is also evidence of benefit for aminosaliclates, bismuth-containing preparations, and if refractory, prednisolone and azathioprine. A small number of patients with microscopic lymphocytic and collagenous colitis have co-existing bile acid malabsorption and as such can respond to cholestyramine. Prognosis is good.

THE COLON AND RECTUM

Structure

The large intestine starts at the caecum, on the posterior medial wall of which is the appendix.

The colon is made up of ascending, transverse, descending and sigmoid parts, which join the rectum at the rectosigmoid junction (Fig. 6.37).

The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taenia coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells with crypts but no villi, so that the surface is flat. The mucosa is full of goblet cells. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. Generally there are good anastomotic channels, but the caecum and splenic flexure are areas where ischaemia can occur. The colon is innervated mainly by the enteric nervous system with input from the parasympathetic and sympathetic pathways. Spinal afferent neurones from the dorsal root ganglia innervate the entire colon.

The rectum is about 12 cm long. Its interior is divided by three crescentic circular muscles producing shelf-like folds. These are the rectal valves that can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

Figure 6.37 Structure of the large intestine.

Table 6.14 Input and output of water and electrolytes in the gastrointestinal tract over 24 hours

	Water (mL)	Sodium (mmol)	Potassium (mmol)
Input			
Diet	1500	150	80
GI secretions	7500	1000	40
Totals	9000	1150	120
Output			
Faeces	150	5	12
Ileostomy (adapted)	500–1000	60–120	4

Physiology of the colon

The main roles of the colon are the absorption of water and electrolytes (Table 6.14) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5–2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from neuroendocrine cells in response to luminal distension. Serotonin activates the HT₄ receptors, which in turn results in the activation of sensory (calcitonin gene-related peptide, CGRP) neurones. Normal colonic transit time is 24–48 h with normal stool weights of up to 250 g/day.

Physiology of defecation

The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by propagated colonic contractions. Sensation of fullness, a desire to defecate and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation the subject sits or squats, contracts the diaphragm and abdominal muscles and relaxes the pelvic floor muscles, including the puborectalis, and the anal sphincter muscles with the result that stool is expelled.

Constipation

'Constipation' is a very common symptom, particularly in women and the elderly. A consensus definition used in research (the Rome III criteria) defines constipation as having two or more of the following for at least 12 weeks: infrequent passage of stools (<3/week), straining >25% of time, passage of hard stools, incomplete evacuation and sensation of anorectal blockage. According to these definitions 'constipation' affects more than one in five of the population.

Many symptoms are attributed by patients to constipation and include headaches, malaise, nausea and a bad taste in the mouth. Other symptoms include abdominal bloating and/or discomfort (undistinguishable from the irritable bowel syndrome) as well as local and perianal pain. The causes of constipation are shown in Table 6.15.

Antimuscarinics
Calcium-channel blockers, e.g. verapamil
Antidepressants, e.g. tricyclics
Iron

Neurological

Spinal cord lesions
Parkinson's disease

Psychological

Depression
Anorexia nervosa
Repressed urge to defecate

Gastrointestinal disease

Intestinal obstruction and pseudo-obstruction
Colonic disease, e.g. carcinoma, diverticular disease
Aganglionosis, e.g. Hirschsprung's disease, Chagas' disease
Painful anal conditions, e.g. anal fissure

Defecatory disorders

Rectal prolapse, mucosal prolapse intussusception and solitary rectal ulcer syndrome
Large rectocele
Pelvic floor dyssynergia/anismus
Megarectum

Figure 6.38 Slow-transit constipation. Straight abdominal X-ray taken on day 6 after ingestion of capsules each containing 20 radio-opaque shapes, which were administered daily on days 1, 2 and 3. All the markers are retained, confirming the diagnosis of severe slow-transit constipation.

Defecatory disorders

A 'paradoxical' contraction rather than the normal relaxation of the puborectalis and external anal sphincter and associated muscles during straining may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is >3 cm. In some patients the mucosa of the anterior rectal wall prolapses downwards during straining (see p. 287) impeding the passage of stool, while in others there may be a higher mucosal intussusception.

In some patients, the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation.

The defecatory disorders can often be characterized by performing evacuation proctography and tests of anorectal physiology.

Slow-transit constipation

Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms include an infrequent urge to defecate, bloating, abdominal pain and discomfort. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of 'meal-stimulated' colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have co-existing disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (see p. 301).

Treatment

Any underlying cause should be treated. In patients with normal and slow-transit constipation the main focus should be directed to increasing the fibre content of the diet in conjunction with increasing fluid intake.

Assessment of constipation

This relies on the history. When there has been a recent change in bowel habit in association with other significant symptoms (e.g. rectal bleeding), a colonoscopy or CT pneumocolon is indicated. By these means, gastrointestinal causes such as colorectal cancer and narrowed segments due to diverticular disease (Table 6.15) can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

- Normal transit through the colon (59%)
- Defecatory disorders (25%)
- Slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

Normal-transit constipation

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal and yet patients believe they are constipated. This is likely to be due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating. Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 20 radio-opaque shapes are swallowed on days 1, 2 and 3 and an abdominal X-ray obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of more than four shapes from the first capsule, six from the second and 12 from the third denotes moderate to severe slow transit (Fig. 6.38).

Box 6.9 Laxatives and enemas

Bulking-forming laxatives

- Dietary fibre
- Wheat bran
- Methylcellulose
- Mucilaginous gums – sterculia
- Mucilaginous seeds and seed coats, e.g. ispaghula husk

Stimulant laxatives (stimulate motility and intestinal secretion)

- Phenolphthalein
- Bisacodyl
- Anthraquinones – senna and dantron (only for the terminally ill)
- Docusate sodium
- Methylnaltrexone (for opioid induced constipation)
- Lubiprostone
- Prucalopride
- Linaclotide
- Sodium picosulfate

Osmotic laxatives

- Magnesium sulphate
- Lactulose
- Macrogols

Suppositories

- Bisacodyl
- Glycerol

Enemas

- Arachis oil
- Docusate sodium
- Hypertonic phosphate
- Sodium citrate

The use of laxatives should be restricted to severe cases. Types of laxatives available are listed in Box 6.9. Osmotic laxatives act by increasing colonic inflow of fluid and electrolytes; this acts not only to soften the stool but to stimulate colonic contractility. The polyethylene glycols (macrogols) have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas which can distend the colon to cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. Prucalopride is a high affinity 5HT₄ agonist which increases colonic transit and is an effective therapy for refractory constipation.

Linaclotide, a minimally absorbed peptide agonist of guanylate cyclase-C receptor, is being used in chronic constipation.

Patients with defecatory disorders should be referred to a specialist centre as surgery may be indicated, for example, for anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.

Miscellaneous colonic conditions

Megacolon

The term 'megacolon' is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances, it is secondary to chronic constipation and in some parts of the world Chagas' disease is a common cause.

All young patients with megacolon should have Hirschsprung's disease excluded. In this disease, which presents in the first years of life, an aganglionic segment of the rectum

Table 6.16 Aetiology of faecal incontinence

Congenital e.g. imperforate anus
Anal sphincter dysfunction Structural damage: Surgery – anorectal, vaginal hysterectomy Obstetric injury during childbirth Trauma Radiation Perianal Crohn's disease Pudendal nerve damage: Childbirth Perineal descent: Prolonged straining at stool
Rectal prolapse
Faecal impaction with overflow diarrhoea
Severe diarrhoea e.g. ulcerative colitis, functional diarrhoea, irritable bowel syndrome
Neurological and psychological disorders Spinal trauma (S2–S4) Spina bifida Stroke Multiple sclerosis Diabetes mellitus (with autonomic involvement) Dementia Psychological illness

(megarectum) gives rise to constipation and subacute obstruction. Occasionally, Hirschsprung's disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained with special stains for ganglion cells in the submucosal plexus. In doubtful cases full-thickness biopsy, under should be obtained. A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung's disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung's disease. This disease can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

Faecal incontinence

Of the healthy population over the age of 65, 7% experience a degree of incontinence. Incontinence occurs when the intrarectal pressure exceeds the intra-anal pressure and is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency). The common causes of incontinence are shown in Table 6.16. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. Endoanal ultrasonography or pelvic MRI are the investigations of choice in the assessment of anal sphincter damage (Fig. 6.39). Neurophysiological investigation of pudendal nerve function, anal sensation and anal sphincter function may be required to elicit the cause of the problem.

Initial *management* of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent which also increases internal sphincter tone.

Biofeedback is effective in some people with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter. Treatment with bulking agent injection is being evaluated.

Figure 6.39 Endoanal ultrasound scan, axial mid canal image, showing a large tear between 10 and 1 o'clock (arrows) following vaginal delivery, involving the external (EAS) and internal anal sphincters (IAS) and resulting in faecal incontinence. (Courtesy of Professor Clive Bartram, Princess Grace Hospital, London.)

Surgery may be required for anal sphincter trauma and should only be carried out in specialist centres.

Ischaemic disease of the colon (ischaemic colitis)

Occlusion of branches of the superior mesenteric artery (SMA) or inferior mesenteric artery (IMA), often in the older age group, commonly presents with sudden onset of abdominal pain and the passage of bright red blood per rectum, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The anatomy of the vascular supply to the colon results in a watershed area at the splenic flexure which is therefore the most common affected site. This condition has also been described in women taking the contraceptive pill, patients on nicorandil and in patients with thrombophilia (see p. 424) and small- or medium-vessel vasculitis (see p. 542).

On *examination* the abdomen may be distended and tender. A straight abdominal X-ray often shows thumb-printing (a characteristic sign of ischaemic disease) at the splenic flexure.

The *differential diagnosis* includes other causes of acute colitis. An unprepared flexible sigmoidoscopy is the investigation of choice: biopsies showing epithelial cell apoptosis and lamina propria fibrosis are characteristic. A colonoscopy should be performed when the patient has fully recovered to exclude the formation of a stricture at the site of disease and confirm mucosal healing. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Treatment

Most patients settle on symptomatic treatment. A few patients show progressive signs of peritonism and imminent perforation and require urgent surgery.

Pneumatosis cystoides intestinalis

This is a rare condition in which multiple gas-filled cysts are found in the submucosa of the intestine, chiefly the colon. The cause is unknown but some cases are associated with chronic obstructive pulmonary disease. Patients are usually asymptomatic, but abdominal pain and diarrhoea do occur and occasionally the cysts rupture to produce a

pneumoperitoneum. This condition is diagnosed on X-ray of the abdomen, barium enema or sigmoidoscopy when cysts are seen.

Treatment is often unnecessary but continuous oxygen therapy will help to disperse the largely nitrogen-containing cysts.

Diverticular disease

Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present throughout the whole colon.

The term *diverticulosis* indicates the presence of diverticula; *diverticulitis* implies that these diverticula are inflamed; diverticular colitis refers to crescentic inflammation on the folds in areas of diverticulosis. It is perhaps better to use the more general term diverticular disease, as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticula formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in developed countries and is rare in rural Africa.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, or even generalized peritonitis.

Clinical features and management

Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on a colonoscopy or barium enema examination. No treatment other than advice to increase dietary fibre is required in those patients. In symptomatic patients intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur. In severe disease, luminal narrowing can occur in the sigmoid colon, giving rise to severe pain and constipation. In the absence of clinical signs of acute diverticulitis a colonoscopy or 'virtual colonoscopy' (see p. 233) is the investigation of choice. Barium enema (Fig. 6.40) combined with flexible sigmoidoscopy is also used. Treatment of uncomplicated symptomatic disease is with a well-balanced (soluble and insoluble) fibre diet (20 g/day) with smooth muscle relaxants if required.

Acute diverticulitis

This most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often accompanied by fever and constipation. These symptoms and signs are similar to appendicitis but on the left side. On examination, the patient is often febrile with a tachycardia. *Abdominal examination* shows tenderness, guarding and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.

Investigations

- **Blood tests.** A polymorphonuclear leucocytosis is often present. The ESR and CRP are raised.
- **CT colonography** (Fig. 6.41) will show colonic wall thickening, diverticula and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with

Figure 6.41 CT of lower abdomen, showing acute diverticulitis (arrow). The bowel wall is thickened and there is loss of clarity of the pericolic fat. A narrow segment of bowel is seen to the left of the diseased segment.

thickening of the pelvic fascial planes. These findings are diagnostic of acute diverticulitis (95% sensitivity and specificity) and differ from those of malignant disease. Sigmoidoscopy and colonoscopy are not performed during an acute attack.

Ultrasound examination is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

Treatment

Mild attacks can be treated on an outpatient basis using oral antibiotics such as ciprofloxacin and metronidazole. Patients with sign of systemic upset (fevers/tachycardia), significant abdominal pain or co-morbidity require admission for bowel rest, i.v. fluids and i.v. antibiotic therapy.

Complications of diverticular disease

- Perforation, which usually occurs in association with acute diverticulitis, can lead to formation of a paracolic

or pelvic abscess or generalized peritonitis. Surgery may be required.

- Fistula formation into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- Intestinal obstruction (see p. 301) usually after repeated episodes of acute diverticulitis.
- Bleeding is sometimes massive. In most cases, the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases, emergency segmental colectomy is required.
- Mucosal inflammation in areas of diverticula occurs, giving the appearance of a segmental colitis at endoscopy which may resemble Crohn's disease. This may cause diarrhoea which responds to 5-ASA therapy.

Anorectal disorders

Pruritus ani

Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually the condition results from haemorrhoids or overactivity of sweat glands. **Treatment** consists of enhanced toilet hygiene, keeping the area dry; and avoiding the use of perfumed moisturizing creams. Secondary causes include threadworm (*Enterobius vermicularis*) infestation, fungal infections (e.g. candidiasis) and perianal eczema, which should be treated appropriately.

Haemorrhoids

Haemorrhoids (primary – internal; second degree – prolapsing; third degree – prolapsed) usually cause rectal bleeding, discomfort and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (Fig. 6.22). Diagnosis is made by inspection, rectal examination and proctoscopy. If symptoms are minor no treatment is required; depending on severity of symptoms, treatment is with rubber band ligation or surgery. Injection of sclerosant is also used, but may be associated with significant complications.

Anal fissures

An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line which produces pain on defecation. It can be an isolated primary problem in young to middle-aged adults or occur in association with Crohn's disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure. Diagnosis can usually be made on the history alone and confirmed on perianal inspection. Rectal examination is often not possible because of pain and sphincter spasm. The spasm not only causes pain but impairs wound healing. In severe cases, proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal disease. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.4% glyceryl trinitrate and 2% diltiazem ointments are of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy is also used for severe cases.

Fistula in ano and anorectal abscesses

The anatomy of perianal fistulae may be simple or complex (Fig. 6.42). The fistulae usually present as abscesses and heal after the abscess is incised. In other cases a small discharging pilonidal sinus may be noted by the patient. Endoanal ultrasonography, magnetic resonance and/or examination under anaesthetic is usually required to define the primary and any secondary tracks, exclude sepsis and detect any associated disease such as Crohn's disease and

tuberculosis. Treatment is with surgical incision and drainage with antibiotics.

Rectal prolapse, intussusception and solitary rectal ulcer syndrome (SRUS)

All these conditions are thought to be related, with rectal prolapse being the unifying pathology. Some patients with SRUS do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during attempts at defecation. Constipation and chronic straining may be precipitating causes. Patients commonly present with slight bleeding and mucus on defecation, tenesmus and sensation of anal obstruction.

SRUS is commonly on the anterior wall of the rectum within 13 cm of the anal verge and this is sometimes difficult to distinguish from cancer and Crohn's disease during endoscopic examination. SRUS has typical histological features of nonspecific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases surgical treatment by resection rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

Colonic tumours

Colon polyps and polyposis syndromes

A colonic polyp is an abnormal growth of tissue projecting from the colonic mucosa. They range from a few millimetres to several centimetres in diameter and are single or multiple, pedunculated, sessile or 'flat'.

Many histological types of polyps are found in the colon (Table 6.17). However, adenomas are the precursor lesions in most cases of colon cancer.

Classification of colorectal polyps (Table 6.17)

Sporadic adenomas. An adenoma is a benign, dysplastic tumour of columnar cells or glandular tissue. They have tubular, tubulovillous or villous morphology. The vast majority of adenomas are not inherited and are termed 'sporadic'. Although many sporadic adenomas do not become malignant in the patient's lifetime, they have a tendency to progress to cancer via increasing grades of dysplasia due to progressive accumulation of genetic changes (adenoma – carcinoma sequence). Factors favouring malignant transformation in colorectal polyps and the relation between adenoma size and likelihood of cancer are shown in Box 6.10.

The progression from benign polyp to cancer is shown in Figure 9.1.

The likelihood of an adenoma being present increases with age; they are rare before the age of 30 years. By the age of 60–70, 5% of asymptomatic subjects will have a polyp of ≥ 1 cm, or cancer with no symptoms, and up to 50% will have at least one small < 1 cm adenoma. Removal of polyps at colonoscopy and subsequent surveillance reduces the risk of development of colon cancer by approximately 80%. It is thought that the remaining 20% are either newly formed, missed, or difficult to detect, e.g. a flat adenoma. Techniques such as chromoscopy using dye spray or narrow band imaging are now being used to assist in their detection (flat adenomas account for approximately 12% of all adenomas).

Polyps in the rectum and sigmoid often present with rectal bleeding. More proximal lesions rarely produce symptoms

Table 6.17 Classification of colorectal polyps and polyposis syndromes

Histology	Polyposis syndrome	Defective gene	Inheritance	CRC risk
Hyperplastic	Hyperplastic polyposis	<i>BRAF</i>		Yes
Hamartoma	Juvenile polyposis	<i>MADH4</i> or <i>BMPR1A</i>	AD	10–70%
	Peutz–Jeghers syndrome	<i>STK11</i>	AD	Yes
	Cowden's syndrome	<i>PTEN</i>	AD	10%?
	Lhermitte–Duclos disorder	<i>PTEN</i>	AD	
	Bannayan–Riley–Ruvalcaba syndrome	<i>PTEN</i>	AD	
Inflammatory	None	None		No
Lymphoid	Benign lymphoid polyposis	Unknown		No
Adenoma	FAP	<i>APC</i>	AD	100%
	AFAP			Yes
	Gardner			Yes
	Turcot		AR	Yes
	MYH-AP	<i>MYH-AP</i>		Yes
Adenoma	HNPCC (Lynch type I or II)	Mismatch repair genes (<i>MSH-2</i> , <i>MLH-1</i>)	AD	70–80%

AD, autosomal dominant; AR, autosomal recessive; AFAP, attenuated FAP; FAP, familial adenomatous polyposis; HNPCC, hereditary non-polyposis colorectal cancer; MLH-1, MutL homologue 1; MSH-2, MutS homologue 2; MYH-AP, MUT Y homologue-associated polyposis; PTEN, phosphatase and tensin homologue.

Box 6.10 Factors affecting risk of malignant change in an adenoma

	Higher risk	Lower risk
Size	>1.5 cm	<1 cm
Type	Sessile or flat	Pedunculated
Histology	Severe dysplasia Villous architecture Squamous metaplasia	Mild dysplasia Tubular architecture
Number	Multiple polyps	Single polyp

and most are diagnosed on barium enema, CT colonography or on colonoscopy performed for screening or for other reasons. Large villous adenomas can present with profuse diarrhoea with mucus and hypokalaemia.

Once a polyp has been found, it is almost always possible to remove it endoscopically. Surveillance guidelines dictate the frequency of repeat investigations:

- At 5 years, if 1 or 2 adenomas <1 cm are found
- At 3 years if there are 3–4 small adenomas or at least one >1 cm
- At 1 year if there are ≥5 small adenomas or there are ≥3, at least one of which is >1 cm.

If any doubt exists about the completeness of excision of any polyp, then an earlier repeat examination is suggested.

Inherited polyposis syndromes

About 5% of colorectal cancers have a well-defined single gene basis.

Familial adenomatous polyposis (FAP) is an autosomal dominant condition arising from germline mutations of the APC gene located on chromosome 5q21–q22. More than 825 different mutations have been identified. Penetrance is virtually 100%. It is characterized by the presence of hundreds to thousands of colorectal and duodenal adenomas. The mean age of adenoma development is 16 years; the average age for developing colorectal cancer is 39 years. Tracing and screening of relatives is essential, usually after 12 years of age, and affected individuals should be offered a prophylactic colectomy, often before the age of 20. Surgical options include colectomy and ileorectal anastomosis which requires lifelong surveillance of the rectal stump, or a

restorative proctocolectomy or pouch procedure with complete removal of rectal mucosa.

Cystic gland polyps, predominantly in the proximal stomach, and duodenal adenomas are frequently found in FAP, as well as other extraintestinal lesions such as osteomas, epidermoid cysts and desmoid tumours. The duodenal adenomas may progress to cancer and are the commonest cause of death in colectomized patients with FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in many families with FAP. Other cancers in FAP include thyroid, pancreatic and hepatoblastomas.

APC gene mutations can be found in about 80% of families with FAP. Once the mutation has been identified in an index case, other family members can be tested for the mutation and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, all family members should undergo clinical screening with regular colonoscopy.

Attenuated FAP may be missed as it presents later (44 years average age) and has fewer polyps (<100), which tend to occur more on the right side of the colon than on the left. It may be indistinguishable from sporadic cases but the gene mutation is in the APC germline.

MYH-associated polyposis. MYH (MUT Y Homologue-associated) polyposis is an autosomal recessive inherited syndrome of multiple colorectal adenomas and cancer. MYH is a base-excision-repair gene that corrects oxidative DNA damage. MYH-AP may account for 7–8% of families with the FAP phenotype in whom APC mutations cannot be found. Subjects with multiple adenomas or an FAP phenotype without APC mutations and with a family history compatible with a recessive pattern of inheritance should be tested for MYH-AP.

Hereditary non-polyposis colon cancer (HNPCC; Lynch syndrome). HNPCC is called 'non-polyposis' to distinguish it from FAP, though polyps are formed in the colon and may progress rapidly to colon cancer. It affects 1:5000 people, causing 3–10% of colorectal cancer cases.

The disease is caused by a mutation in one of the DNA mismatch repair genes, usually *hMSH2* or *hMLH1* but others (*hMSH6*, *PMS1* and *PMS2*) have been reported. Mismatch repair genes are responsible for maintaining the stability of DNA during replication. Inheritance is autosomal dominant. The defect in function of the mismatch repair mechanism

Table 6.18 Diagnostic criteria for hereditary non-polyposis colon cancer (HNPCC)

Modified Amsterdam Criteria
One individual diagnosed with colorectal cancer (or extracolonic HNPCC-associated tumours) before age 50 years
Two affected generations
Three affected relatives, one a 1st-degree relative of the other two
FAP should be excluded
Tumours should be verified by pathological examination
Bethesda Guidelines
Colorectal cancer (CRC) diagnosed in patient who is younger than 50 years
Presence of synchronous, metachronous CRC, or other HNPCC-associated tumours, irrespective of age
CRC with the MSI-H histology diagnosed in a patient who is younger than 60 years
CRC diagnosed in one or more 1st-degree relatives with an HNPCC-related tumour, with one of the cancers being diagnosed under the age 50 years
CRC diagnosed in two or more 1st or 2nd-degree relatives with HNPCC-related tumours, irrespective of age
MSI-H, microsatellite instability – high.

causes naturally occurring highly repeated short DNA sequences known as microsatellites to be shorter or longer than normal, a phenomenon called microsatellite instability (MSI).

Onset of cancer is earlier than in sporadic cases, at age 40–50 or younger. Tumours have a predilection for the right colon, in contrast to sporadic cases. In contrast to FAP, the lifetime risk of colon cancer (penetrance of the gene) in mutation carriers is 70–80%. Other cancers are also more common in HNPCC: stomach, small intestine, bladder, skin, brain and hepatobiliary system. Female patients are at risk for endometrial and ovarian cancer.

The diagnosis is made from the family history of colon cancer at a young age and the presence of associated cancers in the family. These are formalized in the various editions of the Amsterdam and the Bethesda criteria (Table 6.18).

Turcot's syndrome consists of FAP or hereditary non-polyposis colon cancer with brain tumours.

Gardner's syndrome has in addition to FAP desmoid tumours, osteomas of the skull and other lesions.

Hamartomatous polyps are commonly large and stalked. The inherited syndromes show autosomal dominant inheritance and include:

- **Juvenile polyps**, which occur mainly in children and teenagers and are found mainly in the colon and histologically show mucus retention cysts. Most are sporadic, but a syndrome of juvenile polyposis is defined as: >3–5 juvenile colonic polyps, juvenile polyps throughout the GI tract, or any number of polyps with a family history. It is an autosomal dominant condition and the relevant gene has been identified (Table 6.17). The polyps are a cause of bleeding and intussusception in the 1st decade of life. There is also an increased risk of colonic cancer (relative risk (RR) of 34), and surveillance and removal of polyps must be undertaken.
- **Peutz–Jeghers syndrome** (see p. 271).
- **PTEN hamartoma–tumour syndrome** (PHTS), which includes Cowden's syndrome, Bannayan–Riley–Ruvalcaba syndrome and all syndromes caused by germline Phosphatase and Tensin Homolog (PTEN)

Table 6.19 Risk factors in colorectal cancer

Increased risk
Increasing age
Animal fat (saturated) and red meat consumption
Sugar consumption
Colorectal polyps
Family history of colon cancer or colonic polyps
Chronic inflammatory bowel disease
Obesity (body and abdominal)
Smoking
Acromegaly

Exercise (colon only)
Aspirin (including low dose) and other NSAIDs

mutations. Cowden (multiple hamartoma) syndrome is associated with characteristic skin stigmata and intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extraintestinal malignancies (thyroid, breast, uterine and ovarian). These syndromes are uncommon and together account for <1% of colon cancer cases.

- **Hyperplastic (metaplastic) polyps**. These are frequently found in the rectum and sigmoid colon. These pale, sessile mucosal nodules usually measure <5 mm and are normally without significant malignant potential. However, *metaplastic polyposis* is defined as the presence of more than 10 colonic metaplastic polyps, some of which are large. These phenotypes are rare but appear to exhibit an increased risk of colon cancer.

Colorectal carcinoma

Colorectal cancer (CRC) is the third most common cancer worldwide and the second most common cause of cancer death in the UK.

Each year approximately 40 000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer) and it is registered as the cause of death in about half this number. The prevalence rate per 100 000 (at all ages) is 53.5 for men and 36.7 for women. The incidence increases with age; the average age at diagnosis is 60–65 years. Approximately 20% of patients in the UK have distant metastases at diagnosis. The disease is much more common in westernized countries than in Asia or Africa.

Factors related to risk of colorectal cancer are shown in Table 6.19.

Genetics of colorectal cancer

Most colorectal cancers develop as a result of a stepwise progression from normal mucosa to adenoma to invasive cancer. This progression is controlled by the accumulation of abnormalities in a number of critical growth-regulating genes. These include APC mutation and loss, K-ras mutation, Smad2/4 loss, and TP53 mutation and loss, and altered DNA methylation with progression to carcinoma. CDK 8 has recently been found to regulate gene expression in the proliferation of colorectal cancer, and it also regulates the WNT/ beta-catenin signalling pathway (p. 26) involved in many colon cancers. Microsatellite instability (MSI, see p. 288) and chromosomal instability (CIN) are frequently detected in colon cancers. A third group, MACS (Microsatellite And Chromosomal Stable), is also recognized. CIN indicates loss of heterozygosity (LOH) in a number of cancer-related genes,

Figure 6.43 Percentages of colon cancer according to family risk. HNPCC, hereditary non-polyposis colorectal cancer; FAP, familial adenomatous polyposis.

Table 6.20 Lifetime risk of colorectal cancer in 1st-degree relatives of a patient with colorectal cancer

Population risk	1 in 50
One 1st-degree relative affected (any age)	1 in 17
One 1st-degree and one 2nd-degree relative affected	1 in 12
One 1st-degree relative affected (age <45)	1 in 10
Two 1st-degree relatives affected	1 in 6
Autosomal dominant pedigree	1 in 2
Houlston RS, Murday V, Harocopos C et al. Screening and genetic counselling for relatives of patients with colorectal cancer in a family cancer clinic. <i>British Medical Journal</i> 1990; 301:366–368.	

though the underlying mechanisms are not well understood. About 15% of sporadic colorectal cancers show MSI and 50% exhibit LOH.

Cancer families

A family history of CRC confers an increased risk to relatives. Family history is, next to age, the most common risk factor for CRC. FAP (Fig. 6.43) is the best-recognized syndrome predisposing to colorectal cancer but represents less than 1% of all colorectal cancers. Hereditary non-polyposis colorectal cancer (HNPCC) accounts for 3–10% of familial cancer (see p. 288).

Additionally, some colon cancers arise, at least in part, from an inherited predisposition, so-called familial risk (Table 6.20). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a family history matched with empirical risk tables so that appropriate advice regarding screening can be offered.

Most colorectal cancers are, however, sporadic and occur in individuals without a strong family history. Their distribution is shown in Figure 6.44.

Pathology

CRC, which is usually a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent

Figure 6.44 Distribution of sporadic colorectal cancer. Only 60% are in the range of flexible sigmoidoscopy.

spread, most commonly to the liver and lung. Synchronous cancers are present in 2% of cases. Histology is adenocarcinoma with variably differentiated glandular epithelium with mucin production. 'Signet ring' cells in which mucin displaces the nucleus to the side of the cell are relatively uncommon and generally have a poor prognosis.

Clinical features

Symptoms suggestive of colorectal cancer include change in bowel habit with looser and more frequent stools, rectal bleeding, tenesmus and symptoms of anaemia. Looser and more frequent stools, with or without abdominal pain, are common symptoms of left-sided colonic lesions. Rectal and sigmoid cancers often bleed, blood being mixed in with the stool. Presentation with constipation with hard stools is **not** a risk factor for colon cancer. A rectal or abdominal mass may be palpable. Cancers arising in the caecum and right colon are often asymptomatic until they present as an iron deficiency anaemia. Cancer may present with intestinal obstruction.

Patients aged over 35–40 years presenting with new large bowel symptoms should be investigated. Digital examination of the rectum is essential and examination of the colon should be performed in all cases. Hepatomegaly is present if there are large liver metastases.

Investigation

- **Colonoscopy** is the 'gold standard' for investigation and allows biopsy for histology. *Biopsy* of the tumour is mandatory, usually at endoscopy.
- **Double-contrast barium enema** can visualize the large bowel but is now superseded by CT colonography.
- **Endoanal ultrasound and pelvic MRI** are used for staging rectal cancer.
- **Chest, abdominal and pelvic CT** scanning to evaluate tumour size, local spread and liver and lung metastases – this contributes to the tumour staging.
- **PET scanning** is useful for detecting occult metastases and for evaluation of suspicious lesions found on CT or MR.
- **MR** is also useful for evaluating suspicious lesions found on CT or US, especially in the liver.
- **Serum carcinoembryonic antigen (CEA)** is of little use for primary diagnosis and should not be performed as a screening test. It is useful for follow-up; rising levels suggest recurrence.

- **Faecal occult blood tests** are used for mass population screening and are of value in hospital or general practice.

Treatment

Treatment should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery (often laparoscopically), though fewer than half of these survive more than 5 years. The operative procedure depends on the cancer site. Long-term survival relates to the stage of the primary tumour and the presence of metastatic disease. There has been a gradual move from using Dukes' classification to using the TNM classification system (see p. 477). Long-term survival is only likely when the cancer is completely removed by surgery with adequate clearance margins and regional lymph node clearance.

- **Total mesorectal excision (TME)** is required for rectal cancers and removes the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision which requires a permanent colostomy is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Pre- or postoperative chemotherapy reduces local recurrence rates but had no effect on survival in a recent study.
- **A segmental resection** and restorative anastomosis with removal of the draining lymph nodes as far as the root of the mesentery is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction so surgery can be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.
- **Local transanal surgery** is very occasionally used for early superficial rectal cancers.
- **Surgical or ablative treatment of liver and lung metastases** prolongs life where treatment is technically feasible and the patient is fit enough to undergo the treatment.
- **Radiotherapy is not helpful for colonic cancers** proximal to the rectum because of difficulties delivering a sufficient dose to the tumour without excess toxicity to adjacent structures, particularly the small bowel.
- **Adjuvant postoperative chemotherapy** improves disease-free survival and overall survival in stage III (Dukes' C) colon cancer (see p. 478). Those with Dukes' B tumours with advanced features such as vascular invasion may also benefit.

Treatment of advanced colorectal cancer is discussed on page 477.

Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second 'clearance' colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. Annual CT scanning of the chest and abdomen to detect operable

liver metastases should be performed for up to 3 years post-surgery.

Screening for CRC

- **Faecal occult blood (FOB) tests** have been studied as a screening test for colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15–33%. Immunological based FOB tests are superior to the conventional guaiac based systems. The disadvantage of screening with FOB is its relatively low sensitivity, which means many negative colonoscopies. In FOBT screen-positive patients in the UK National Bowel Cancer Screening Programme (NHS BCSP), about 10% have cancer, 40% have adenomas and the colon is normal in 50%.
- **Flexi-sigmoidoscopy** screening has been shown to reduce the mortality from CRC but not overall mortality.
- **Colonoscopy** is the 'gold standard' technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present.
- **CT colonography** ('virtual colonoscopy') (see Fig. 6.5) is being increasingly used.
- Genetic testing and stool DNA tests also contribute to screening programmes.

DIARRHOEA

Diarrhoea is a common clinical problem and there is no uniformly accepted definition of diarrhoea. Organic causes (stool weights >250 g/day) have to be distinguished from functional causes. Sudden onset of bowel frequency associated with crampy abdominal pains, and a fever will point to an infective cause; bowel frequency with loose blood-stained stools to an inflammatory basis; and the passage of pale offensive stools that float, often accompanied by loss of appetite and weight loss, to steatorrhoea. Nocturnal bowel frequency and urgency usually point to an organic cause. Passage of frequent small-volume stools (often formed) points to a functional cause (see Functional gastrointestinal disorders, below).

Mechanisms

Osmotic diarrhoea

The gut mucosa acts as a semipermeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because:

- The patient has ingested a non-absorbable substance (e.g. a purgative such as magnesium sulphate or magnesium-containing antacid)
- The patient has generalized malabsorption so that high concentrations of solute (e.g. glucose) remain in the lumen
- The patient has a specific absorptive defect (e.g. disaccharidase deficiency or glucose-galactose malabsorption).

The volume of diarrhoea produced by these mechanisms is reduced by the absorption of fluid by the ileum and colon. The diarrhoea stops when the patient stops eating or the malabsorptive substance is discontinued.

Diarrhoea

Figure 6.45 Mechanisms of diarrhoea.

(a) Small intestinal secretion of water and electrolytes. *Cholera toxin* binds to its receptor (monosialoganglioside G_s) via fimbria (toxin co-regulated pilus) on its β -subunit. This activates the α_s subunit (of the G_s protein), which in turn dissociates and activates cyclic AMP (cAMP). The increase in cAMP activates intermediates (e.g. protein kinase and Ca^{2+}) which then act on the apical membrane causing Cl^- secretion (with water) and inhibition of Na^+ and Cl^- absorption. Heat-labile *E. coli* enterotoxin shares a receptor with cholera toxin. Heat-stable (HS) *E. coli* toxin binds to its own receptor and activates guanylate cyclase (cGMP), producing the same effect on secretion. *C. difficile* activates the protein kinases via Ca^{2+} /calmodulin (Ca^{2+} /CM). *Zona occludens toxin* is the product of the *ZOT* gene, which is the gene required for the *CTX* gene which encodes for cholera toxin. It has enterotoxic activity, producing secretion. Cholera and *E. coli* cause these effects without invasion of the cell. G, G protein consisting of subunits α , β , γ ; i, inhibitory; s, stimulatory; ATP, adenosine triphosphate; GTP, guanosine triphosphate; GMP, guanosine monophosphate; GC, guanyl cyclase; PKC, protein kinase C; VIP, vasoactive intestinal polypeptide.

(b) Colonic mucosal cell. This demonstrates one of the mechanisms by which an invasive pathogen (e.g. *Shigella*) acts. Following penetration, the pathogens generate cytotoxins which lead to mucosal ulceration and cell death.

Secretory diarrhoea

In this disorder, there is both active intestinal secretion of fluid and electrolytes as well as decreased absorption. The mechanism of intestinal secretion is shown in Figure 6.45a.

Common causes of secretory diarrhoea are:

- Enterotoxins (e.g. cholera, *E. coli* thermolabile or thermostable toxin, *C. difficile*)
- Hormones (e.g. vasoactive intestinal peptide in the Verner–Morrison syndrome, p. 370)
- Bile salts (in the colon) following ileal resection
- Fatty acids (in the colon) following ileal resection
- Some laxatives (e.g. docusate sodium).

Inflammatory diarrhoea (mucosal destruction)

Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and blood (Fig. 6.45b). In addition, there is defective absorption of fluid and electrolytes. Common causes are infective conditions (e.g. dysentery due to *Shigella*) and inflammatory conditions (e.g. ulcerative colitis and Crohn's disease).

Abnormal motility

Diabetic, post-vagotomy and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. Symptoms may be exacerbated by small bowel bacterial overgrowth.

Causes of diarrhoea are shown in Table 6.21. It should be noted that the irritable bowel syndrome, colorectal cancer,

diverticular disease and faecal impaction with overflow in the elderly do not cause 'true' organic diarrhoea (i.e. >250 g/day), even though the patients may complain of diarrhoea. Worldwide, infection and infestation are a major problem and these are discussed under the causative organisms in Chapter 4.

Acute diarrhoea (excluding cholera – see p. 103)

Diarrhoea of sudden onset is very common, often short-lived and requires no investigation or treatment. Although dietary causes should be considered, diarrhoea due to viral agents may also last 24–48 hours (see p. 103). The causes of other infective diarrhoeas are shown on page 119. Travelers' diarrhoea, which affects people travelling outside their own countries, particularly to developing countries, usually lasts 2–5 days; it is discussed on page 122. Clinical features associated with the acute diarrhoeas include fever, abdominal pain and vomiting. If the diarrhoea is particularly severe, dehydration can be a problem; the very young and very old are at special risk from this. Investigations are necessary if the diarrhoea has lasted more than 1 week. Stools (up to three) should be sent immediately to the laboratory for culture and examination for ova, cysts and parasites and *Clostridium difficile* toxin assay. If the diagnosis has still not been made, a sigmoidoscopy and rectal biopsy should be performed and imaging should be considered. Viral and bacterial infective diarrhoeas do not last more than two weeks.

Table 6.21 Causes of diarrhoea**Infective causes**

Bacterial, e.g.
Campylobacter jejuni
Salmonella spp.
Shigella
Escherichia coli (p. 121)
 Staphylococcal enterocolitis
Bacillus cereus
Clostridium perfringens, *botulinum*, *difficile*
 gastrointestinal tuberculosis
 Viral, e.g.
 rotavirus
 Fungal, e.g.
 histoplasmosis
 Parasitic, e.g.
 amoebic dysentery (*Entamoeba histolytica*)
 schistosomiasis
Giardia intestinalis

Non-infective causes of diarrhoea

Inflammatory bowel disease
 Radiation proctitis or colitis
 Behçet's disease
 Diverticular disease
 Ischaemic colitis
 Gastrointestinal lymphoma
 Carcinoma of the colon (change in bowel habit)
 Malabsorption
 Gut resection
 Bile acid malabsorption
 Drugs – many, including
 laxatives
 metformin
 anticancer drugs
 statins
 proton pump inhibitors
 Faecal impaction with overflow
 Irritable bowel syndrome and functional diarrhoea

Endocrine

Zollinger–Ellison syndrome
 VIPoma
 Somatostatinoma
 Glucagonoma
 Carcinoid syndrome
 Thyrotoxicosis
 Medullary carcinoma of thyroid
 Diabetic autonomic neuropathy

Factitious diarrhoea

Purgative abuse
 Dilutional diarrhoea

Table 6.22 Causes of bile acid diarrhoea

Ileal resection
 Ileal disease, e.g. active or inactive Crohn's disease
 Primary bile acid diarrhoea
 Postinfective gastroenteritis
 Rapid small bowel transit
 Post-cholecystectomy

C. difficile-associated diarrhoea (pseudomembranous colitis)

Pseudomembranous colitis (see p. 122) may develop following the use of any antibiotic. Diarrhoea occurs in the first few days after taking the antibiotic or even up to 6 weeks after stopping the drug. The causative agent is *Clostridium difficile* (see p. 122).

Bile acid malabsorption

Bile acid malabsorption is an underdiagnosed cause of chronic diarrhoea and many patients with this disorder are assumed to have irritable bowel syndrome. Bile acid diarrhoea occurs when the terminal ileum fails to reabsorb bile acids. Bile acids (particularly the dihydroxy bile acids: deoxycholate and chenodeoxycholate) when present in increased concentrations in the colon lead to diarrhoea by reducing absorption of water and electrolytes and, at higher concentrations, inducing secretion as well as increasing colonic motility. A variety of causes of bile acid malabsorption are recognized (Table 6.22).

Bile acid malabsorption should be considered not only in patients with chronic diarrhoea of unknown cause but also in patients with diarrhoea and associated disease who are not responding to standard therapy (e.g. patients with terminal ileal Crohn's disease, microscopic inflammatory colitis).

Diagnosis is made using the SeHCAT test in which a radiolabelled bile acid analogue is administered and percentage retention at 7 days calculated (<19% retention abnormal). Treatment is with bile salt sequestrants such as cholestyramine, a resin which binds and inactivates the action of bile acids in the colon. The best results of treatment are obtained in patients with a SeHCAT retention of <5%.

Factitious diarrhoea

Factitious diarrhoea accounts for up to 4% of new patients with diarrhoea attending gastroenterology clinics.

Purgative abuse

This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (>1 L daily) and patients may have a low serum potassium. Biochemical analysis of the stool may help diagnose laxative abuse. Management is difficult as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and patients may need psychiatric help.

Dilutional diarrhoea

In this condition, raised stool weights occur as a consequence of patients deliberately diluting their stool with urine or tap water. The diagnosis is made by measuring stool

Oral fluid and electrolyte replacement is often necessary. Special oral rehydration solutions (e.g. sodium chloride and glucose powder) are available for use in severe episodes of diarrhoea, particularly in infants. Antidiarrhoeal drugs are thought to impair the clearance of any pathogen from the bowel but may be necessary for short-term relief (e.g. codeine phosphate 30 mg four times daily or loperamide 2 mg three times daily). Antibiotics are occasionally necessary (see p. 125) depending on the organism.

Chronic diarrhoea

This always needs investigation. The flow diagram in Figure 6.46 is illustrative; whether the large or the small bowel is investigated first will depend on the clinical story of, for example, bloody diarrhoea or steatorrhoea. The investigations and treatment are described in detail under the individual diseases. Colonoscopy is usually necessary if stool cultures are negative and small bowel disease is not suspected.

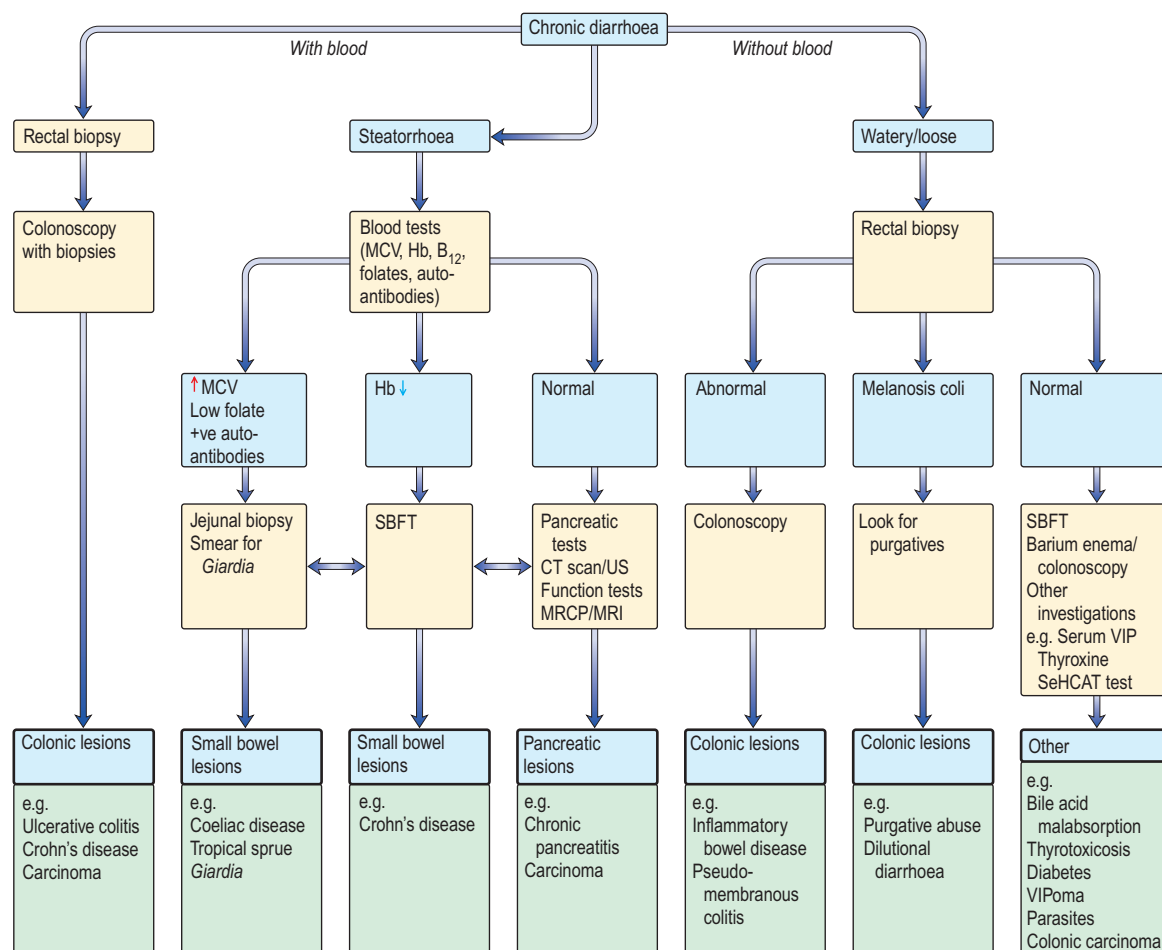

Figure 6.46 Flow diagram for the investigation of chronic diarrhoea. Note: All patients should have had stool cultures with toxin testing for *C. difficile*. SBFT, small bowel follow-through; VIP, vasoactive intestinal polypeptide; MRCP, magnetic resonance cholangiopancreatography; SeHCAT, ⁷⁵Se-homocholic acid taurine.

osmolality and electrolyte concentrations in order to calculate the faecal osmolar gap.

Diarrhoea in patients with HIV infection

Chronic diarrhoea is a common symptom in HIV infection, but HIV's role in the pathogenesis of diarrhoea is unclear. *Cryptosporidium* (see p. 110) is the pathogen most commonly isolated. *Isospora belli* and microsporidia have also been found.

The cause of the diarrhoea is often not found and treatment is symptomatic. Table 6.23 shows the conditions affecting the gastrointestinal tract in patients with AIDS.

FUNCTIONAL GASTROINTESTINAL DISORDERS

There is a large group of gastrointestinal disorders that are termed 'functional' because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients, fluid and electrolytes and no structural abnormality can be identified in the gastrointestinal tract, although there may be discernible abnormalities in neuromuscular function such as dysmotility and visceral hypersensitivity, which are not routinely investigated.

Table 6.24 lists some of the symptoms that are suggestive of a functional gastrointestinal disorder. Modern

classification systems are based on the premise that for each disorder there is a symptom cluster that 'breeds true' across clinical and population groups. There is inevitably overlap, with some symptoms being common to more than one disorder.

Table 6.25 lists the common functional gastrointestinal disorders as defined by Rome III criteria. These conditions are extremely common worldwide, comprising 80% of patients seen in the gastroenterology clinic.

Pathophysiology and brain-gut interactions

People with functional gastrointestinal disorders (FGID) are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and symptoms in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hypersensitivity possibly relates to:

- Altered receptor sensitivity at the viscus itself
- Increased excitability of the spinal cord dorsal horn neurones
- Altered central modulation of sensations.

Table 6.23	Gastrointestinal problems in patients with AIDS	
Symptoms	Causes	
Mouth/oesophagus		
Dysphagia	Herpes simplex virus (HSV)	
Retrosternal discomfort	Cytomegalovirus (CMV)	
Oral ulceration	Candidiasis	
Small bowel/colon		
Chronic diarrhoea	Parasites:	
Steatorrhoea	<i>Entamoeba histolytica</i>	
Weight loss	<i>Giardia intestinalis</i>	
	<i>Cryptosporidium</i>	
	<i>Blastocysts hominis</i>	
	<i>Isospora belli</i>	
	<i>Microsporidia</i>	
	<i>Cyclospora cayetanensis</i>	
	Viruses:	
	CMV/HSV, adenovirus	
	Bacteria:	
	<i>Salmonella</i>	
	<i>Campylobacter</i>	
	<i>Shigella</i>	
	<i>Mycobacterium avium-intracellulare</i>	
	Non-infective enteropathy – cause unknown	
Rectum/colon		
Bloody diarrhoea	Bacterial infection (e.g. <i>Shigella</i>)	
Any site		
Weight loss	Neoplasia:	
Diarrhoea	Kaposi's sarcoma	
	Lymphoma	
	Squamous carcinoma	
	Infection – disseminated, e.g.	
	<i>Mycobacterium avium-intracellulare</i>	
	HAART therapy	

Table 6.24	Chronic gastrointestinal symptoms suggestive of a functional gastrointestinal disorder (FGID)
Nausea alone	
Vomiting alone	
Belching	
Chest pain unrelated to exercise	
Postprandial fullness	
Abdominal bloating	
Abdominal discomfort/pain (right or left iliac fossa)	
Passage of mucus per rectum	
Frequent bowel actions with urgency first thing in morning	

Symptoms are thought to be due to disturbed gastrointestinal motility that leads to distension with visceral hyperalgesia accentuating the pain but there are no data to confirm this. A systematic review of published studies suggest that 10% of patients who experience an acute infective gastroenteritis develop a degree of FGID. It is not clear whether this is caused by post-infectious bile salt malabsorption, alterations in the mucosal immune system or the use of antibiotics to treat the index infection.

The brain–gut axis describes a combination of intestinal motor, sensory and CNS activities (Fig. 6.47). Thus extrinsic (e.g. vision, smell) and intrinsic (e.g. emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotrophic events can affect central pain perception, mood and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more

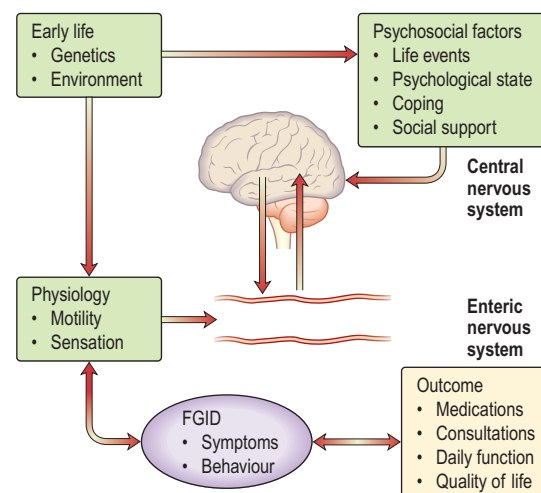

Figure 6.47 A biopsychosocial conceptualization of the pathogenesis and clinical expression of functional gastrointestinal disorders (FGIDs), showing how genetic, environmental and psychological factors may interact to cause dysregulation of brain–gut function. (Modified from Drossman DA. The functional gastrointestinal disorders and the Rome III process. *Gastroenterology* 2006; 130:1377–1390, with permission from Elsevier.)

common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g. family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity). Therefore, FGID should be regarded as a dysregulation of brain–gut function.

Functional oesophageal disorders

The criteria for diagnosis rest mainly on compatible symptoms. However, *pathological gastro-oesophageal* reflux and eosinophilic oesophagitis may need to be excluded (see p. 244).

Globus

This presents as:

- Persistent or intermittent sensation of a lump or foreign body in the throat
- Occurrence of the sensation between meals
- The absence of dysphagia and pain on swallowing (odynophagia).

Treatment is with explanation and reassurance and a trial of antireflux therapy. Antidepressants may be tried.

Functional chest pain, of presumed oesophageal origin

This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and which occur in the absence of a cardiological cause, gastro-oesophageal reflux and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers.

Antidepressant therapy, e.g. amitriptyline or the selective serotonin reuptake inhibitor citalopram, have been shown to be effective.

Functional gastroduodenal disorders

Functional dyspepsia

This is the second most common functional gastrointestinal disorder (after irritable bowel syndrome). Patients can present with a spectrum of symptoms including upper abdominal pain/discomfort, fullness, early satiety, bloating and nausea.

These patients have no structural abnormality as an explanation for their symptoms.

Functional dyspepsia subgroups

Two subgroups based on the predominant (or most bothersome) single symptoms are suggested:

- **Epigastric pain syndrome** with pain centred in the upper abdomen as the predominant (most bothersome) symptom.
- **Postprandial distress syndrome** with an unpleasant or troublesome non-painful sensation (discomfort) centred in the upper abdomen being the predominant symptom. This sensation may be associated with upper abdominal fullness, early satiety, bloating and nausea.

There is considerable overlap between these two groups.

Investigations

Helicobacter pylori infection should be serologically excluded, but many young patients (<50) require no further investigation. Older patients or those with alarm symptoms require endoscopy. Gastroscopy often shows gastritis but whether this is the cause of the symptoms is doubtful.

Treatment

The range of therapies prescribed for functional dyspepsia reflects the uncertain pathogenesis and the lack of satisfactory treatment options. Management is further confounded by high placebo response rates (20–60%). A proportion of patients will respond satisfactorily to reassurance, explanations and lifestyle changes. Proton pump inhibitors and prokinetic agents are used for patients with epigastric pain syndrome and postprandial distress syndrome, respectively.

Reducing intake of fat, coffee, alcohol and cigarette smoking helps. SSRI medication is tried in refractory cases.

H. pylori eradication therapy has been shown to be effective in some patients with functional dyspepsia.

Aerophagia

Aerophagia refers to a repetitive pattern of swallowing or ingesting air and belching. It is usually an unconscious act unrelated to meals. Usually no investigation is required. Explanation that the symptoms are due to swallowed air and reassurance are necessary, as is treatment of associated psychiatric disease.

Functional vomiting

Functional vomiting is a rare condition in clinical practice, although chronic nausea is a frequent accompaniment in all functional gastrointestinal disorders. CNS pathology and migrainous syndromes (cyclical vomiting syndrome) should be considered and treated. Clinically, functional vomiting is characterized by:

- Frequent episodes of vomiting, occurring on at least 1 day a week
- Absence of criteria for an eating disorder, rumination or major psychiatric disease
- Absence of self-induced and medication-induced vomiting
- Absence of abnormalities in the gut or central nervous system and metabolic disease to explain the recurrent vomiting.

Investigation is often not required but always exclude non-GI disorders (see Table 6.1).

Treatment is with anti-nausea drugs and antidepressants; behavioural therapy and psychotherapy are helpful. Dietary changes occasionally help.

Functional bowel disorders

Irritable bowel syndrome (IBS)

IBS is the commonest FGID. In western populations, up to one in five people report symptoms consistent with IBS. Approximately 50% will consult their doctors and of these up to 30% will be referred by their doctor to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as GB£45.6 million; in the USA, the cost is higher at US\$8 billion. In the UK, approximately one-quarter of IBS patients lose time off work for periods ranging from 7 to 13 days each year.

The factors that determine whether an IBS sufferer in the community seeks medical advice include higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are severer than non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consulters outnumber male consulters by a factor of 2–3.

IBS – a multisystem disorder

IBS patients suffer from a number of non-intestinal symptoms (Table 6.26), which may be more intrusive than the classical features. IBS co-exists with chronic fatigue syndrome (see p. 1162), fibromyalgia (see p. 509) and temporomandibular joint dysfunction.

Table 6.26 Non-gastrointestinal features of irritable bowel syndrome

Gynaecological symptoms
Painful periods (dysmenorrhoea)
Pain following sexual intercourse (dyspareunia)
Urinary symptoms
Frequency
Urgency
Passing urine at night (nocturia)
Incomplete emptying of bladder
Other symptoms
Joint hypermobility
Back pain
Headaches
Bad breath, unpleasant taste in the mouth
Poor sleeping
Fatigue

Table 6.27 Subtyping irritable bowel syndrome by predominant stool pattern

IBS with constipation (IBS-C)	Hard lumpy stools >25% and loose (mushy) or watery stools <25% of bowel movements
IBS with diarrhoea (IBS-D)	Loose (mushy) or watery stools >25% and hard or lumpy stools <25% of bowel movements
Mixed IBS (IBS-M)	Hard or lumpy stools >25% and loose (mushy) or watery stools >25% of bowel movements
Unsubtyped IBS	Insufficient abnormality of stool consistency to meet criteria for IBS-C, D or M

Box 6.11 Some factors that can trigger onset of irritable bowel symptoms

- Affective disorders, e.g. depression, anxiety
- Psychological stress and trauma
- Gastrointestinal infection
- Antibiotic therapy
- Sexual, physical, verbal abuse
- Pelvic surgery
- Eating disorders

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs (Fig. 6.48) is particularly relevant to IBS and Box 6.11 lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7–30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female gender, severity and duration of diarrhoea, pre-existing life events and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients and stress or adverse life events often precede the onset of chronic bowel symptoms.

Diagnostic criteria (Rome III 2006)

These criteria state that in the preceding 3 months, there should be at least 3 days/month of recurrent abdominal pain or discomfort associated with two or more of the following:

1. Improvement with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool.

These are useful for comparative studies.

Subgroups of IBS patients can be identified according to the criteria listed in Table 6.27.

The decision as to whether to investigate and the choice of investigations should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss and a clinical suspicion of organic diarrhoea. A raised stool calprotectin or lactoferrin would suggest inflammation needing further investigation.

Treatment

Current strategies for treatment of IBS include therapies that target central and end-organ pathways (Box 6.12) and are

Box 6.12 Approaches to management of the irritable bowel syndrome (IBS)

Action	
End organ treatment	
Explore dietary triggers	Refer to dietitian
High-fibre diet ± fibre supplements for constipation FODMAP diet for bloating	Refer to dietitian
Alter the microbiota	Rifaximin has shown short-term benefit in IBS patients without Pro- and pre-biotics constipation (Target I and II trials)
Anti-diarrhoeal drugs for bowel frequency	Loperamide Codeine phosphate Co-phenotrope
Constipation	5HT ₄ receptor agonist, e.g. prucalopride
Smooth muscle relaxants for pain	Mebeverine hydrochloride Dicycloverine hydrochloride Peppermint oil
Central treatment	
Explain physiology and symptoms	At consultation (leaflets with diagrams help)
Psychotherapy	Refer to clinical psychologist (see p. 1163)
Hypnotherapy	
Cognitive behavioural therapy	Refer to psychiatrist
Antidepressants	Functional diarrhoea – clomipramine Diarrhoea-predominant IBS – tricyclic group, e.g. amitriptyline Constipation-predominant IBS – SSRI, e.g. paroxetine

not mutually exclusive. HT₄ receptor agonists for constipation-predominant IBS (prucalopride) are now licensed for use in many countries, although the 5HT₃ drugs designed to treat diarrhoea-associated IBS await regulatory approval.

Probiotics and prebiotics

Probiotics are live or attenuated bacteria or bacterial products that confer a significant health benefit to the host. Recent studies have shown a beneficial effect of specific probiotics such as *Bifidobacterium infantis* 35624 on IBS symptoms. However, problems with quality control and formulation of probiotics are currently restricting the clinical availability of some probiotics.

FURTHER READING

Drossman DA. The functional gastrointestinal disorders and the Rome III process. *Gastroenterology* 2006; 130: 1377–1390.

Prebiotics are non-digestible food supplements that are fermented by host bacteria thereby altering the microbiota of the host often by stimulating the growth of healthy bacteria. There is early evidence that they may have a beneficial impact on some IBS symptoms.

Pain/gas/bloat syndrome/midgut dysmotility

There exist a group of patients with functional bowel disease whose abdominal pain and other clinical features are likely to occur as a consequence of disordered motility and visceral sensation that predominantly affects the small intestine or midgut. The symptom-based diagnostic criteria are abdominal pain, often exacerbated by eating and not relieved by opening the bowels and not associated with the passage of more frequent or looser stools than normal and not associated with constipation. Other symptoms include abdominal distension (bloating), postprandial fullness, nausea and, on occasions, anorexia and weight loss.

Treatment of patients with pain/gas/bloat syndrome is not easy; and in some, pain can be chronic and severe. Narcotics should always be avoided. Central and end-organ targeted treatment approaches should be combined, e.g. selective serotonin reuptake inhibitor paroxetine combined with a prokinetic agent domperidone or smooth muscle relaxant, e.g. mebeverine. Patients can be referred to a dietician for a trial of a FODMAP (fermentable oligo-, di- and mono-saccharides and polyols) diet. Small bowel bacterial overgrowth can be a contributory feature.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms which may be nocturnal. A small subgroup of these has been shown to have manometric features consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (CIIP), and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies confirm this diagnosis by showing a deficiency of α actin staining in the inner circular layer of smooth muscle. More appropriately these patients should be considered to have a gastrointestinal neuromuscular disorder of the gut. About 10% of these patients are subsequently found to have an underlying autoimmune overlap disorder (see p. 541).

Treatment of patients with neuromuscular disorders of the gut requires a multidisciplinary approach, with emphasis on management of pain, psychological state and nutrition. Patients with underlying autoimmune inflammatory mixed connective tissue disorders may benefit from primary treatment of these. Patients with intestinal failure as a result of CIIP need long-term parenteral nutrition.

Functional diarrhoea

In this form of functional bowel disease, symptoms occur in the absence of abdominal pain and commonly are:

- The passage of several stools in rapid succession usually first thing in the morning. No further bowel action may occur that day or defecation only after meals
- The first stool of the day is usually formed, the later ones are mushy, looser or watery
- Urgency of defecation
- Anxiety, uncertainty about bowel function with restriction of movement (e.g. travelling)
- Exhaustion after the defecation.

Chronic diarrhoea without pain is caused by many diseases indistinguishable by history from functional diarrhoea.

Table 6.28 Common causes of acute abdominal pain

Diagnosis	%
Nonspecific abdominal pain	35
Acute appendicitis	30
Gall bladder disease	10
Gynaecological disorders	5
Intestinal obstruction	5
Perforated ulcer/dyspepsia	5
Renal colic	2
Urinary tract infection	2
Diverticular disease	2
Other diagnoses	4
Percentages are approximate and vary in different communities.	

Features atypical for a functional disorder (e.g. large-volume stools, rectal bleeding, nutritional deficiency and weight loss) call for more extensive investigations.

Treatment of functional diarrhoea is with loperamide often combined with a tricyclic antidepressant prescribed at night (e.g. clomipramine 10–30 mg).

THE ACUTE ABDOMEN

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Table 6.28). If recognized quickly as an emergency, reduction in morbidity and mortality can be achieved. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an 'acute abdomen' exists and whether surgery is required.

History

This should include previous operations, any gynaecological problems and whether any concurrent medical condition is present.

Pain

The onset, site, type and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can either be constant (usually owing to inflammation) or colicky because of a blocked 'tube'. The inflammatory nature of a constant pain will be supported by a raised temperature, tachycardia and/or a raised white cell count. If these are normal, then other causes (e.g. musculoskeletal, aortic aneurysm) or rare causes (e.g. porphyria) should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system or the uterus. These will probably initially require conservative management along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g. strangulated hernia, ascending cholangitis or salpingitis).

A sudden onset of pain suggests:

- Perforation (e.g. of a duodenal ulcer)
- Rupture (e.g. of an ectopic pregnancy)
- Torsion (e.g. of an ovarian cyst)
- Acute pancreatitis
- Infarction (e.g. mesenteric).

Back pain suggests:

- Pancreatitis
- Rupture of an aortic aneurysm
- Renal tract disease.

FURTHER READING

Moayyedi P, Ford AC, Talley NJ et al. The efficacy of probiotics in the treatment of irritable bowel syndrome: a systematic review. *Gut* 2010; 59:325–332.

Inflammatory conditions (e.g. appendicitis) produce a more gradual onset of pain. With peritonitis the pain is continuous and may be made worse by movement. Many inflammatory conditions can progress to those listed in sudden onset due to complications.

Vomiting

Vomiting may accompany any acute abdominal pain but, if persistent, it suggests an obstructive lesion of the gut. The character of the vomit should be asked – does it contain blood, bile or small bowel contents?

Other symptoms

Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history including LMP should be taken.

Physical examination

The general condition of the person should be noted. Does the person look ill? Is he or she shocked? Large volumes of fluid may be lost from the vascular compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia, i.e. a pale cold skin, a weak rapid pulse and hypotension.

The abdomen

- **Inspection.** Look for the presence of scars, distension or masses.
- **Palpation.** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and it indicates peritonitis. This can be localized to one area or it may be generalized, involving the whole abdomen.
- **Bowel sounds.** Increased high-pitch tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the dilated bowel lumen. Absent bowel sounds suggest peritonitis. In an obstructed patient, absent bowel sounds suggest strangulation, ischaemia or ileus. It is essential that the hernial orifices be examined if intestinal obstruction is suspected.

Vaginal and rectal examination

Vaginal examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g. a ruptured ectopic pregnancy). Rectal examination is less helpful as localized tenderness may be due to any cause; it may show blood on the glove.

Flexible sigmoidoscopy

If diarrhoea is present, unprepared (without use of laxative bowel preparation or enema) flexible sigmoidoscopy may be indicated to aid exclusion of infective, inflammatory and ischaemic causes of acute pain. A specimen of stool should be taken for stool culture for bacterial pathogens (e.g. *Campylobacter*, *Salmonella*, *Shigella* and *Clostridium difficile* toxin) (see p. 174).

Other observations

- **Mouth.** The tongue is furred in some cases and a fetor is present.
- **Temperature.** Fever is more common in acute inflammatory processes.
- **Urine.** Examine for:
 - blood – suggests urinary tract infection or renal colic
 - glucose and ketones – ketoacidosis can present with acute pain

Table 6.29 Medical causes of acute abdomen

Peri-aortitis

Figure 6.48 X-ray showing air under the diaphragm.

- protein and white cells – to exclude acute pyelonephritis.

- Think of medical causes (Table 6.29).

Investigations

- **Blood count.** A raised white cell count occurs in inflammatory conditions.
- **Serum amylase.** High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.
- **Serum electrolytes.** These are not particularly helpful for diagnosis but useful for general evaluation of the patient.
- **Pregnancy test.** A urine dipstick is used for women of childbearing age.
- **X-rays.** A chest X-ray is useful to detect air under the diaphragm owing to a perforation (Fig. 6.48). Dilated loops of bowel or fluid levels are suggestive of obstruction (erect and supine abdominal X-ray) (Fig. 6.49).

Figure 6.49 X-ray showing small bowel obstruction.

- **Ultrasound.** This is useful in the diagnosis of acute cholangitis, cholecystitis and aortic aneurysm, and in expert hands is reliable in the diagnosis of acute appendicitis. Gynaecological and other pelvic causes of pain can be detected.
- **CT scan.** Spiral CT of abdomen and pelvis is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.
- **Laparoscopy.** This has gained increasing importance as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of 50 years. In addition, therapeutic manoeuvres, such as appendicectomy, can be performed.

Acute appendicitis

This is a common surgical emergency. It affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

Clinical features and management

Most patients present with abdominal pain; in many it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa. Although raised white cell counts, ESR and CRP are helpful, other laboratory tests can be unhelpful. An ultrasound scan can detect an inflamed appendix and can also indicate an appendix mass or other localized lesion. CT is highly sensitive (98.5%) and specific (98% negative predictive value; 99.5% positive predictive value), and reduces the incidence of removing the 'normal' appendix. With the use of these investigations the incidence of 'normal' appendix histology has fallen to 15–20%.

Differential diagnosis

- Nonspecific mesenteric lymphadenitis – may mimic appendicitis

- Acute terminal ileitis due to Crohn's disease or *Yersinia* infection
- Gynaecological causes
- Inflamed Meckel's diverticulum
- Functional bowel disease.

Treatment

The appendix is removed by laparoscopic surgery. If an appendix mass is present, the patient is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

Gynaecological causes

Ruptured ectopic pregnancy. The fallopian tube is the commonest extrauterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

Ovarian:

- Rupture of 'functional' ovarian cysts in the middle of the cycle (Mittelschmerz)
- Torsion or rupture of ovarian cysts.

Acute salpingitis. Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever and vaginal discharge. In the Fitz-Hugh–Curtis syndrome the *Chlamydia* infection tracks up the right paracolic gutter to cause a perihepatitis. Patients can present with acute right hypochondrial pain, fever and mildly abnormal liver biochemistry.

Acute peritonitis

Localized peritonitis

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g. acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

Generalized peritonitis

This is a serious condition, resulting from irritation of the peritoneum owing to infection (e.g. perforated appendix) or from chemical irritation due to leakage of intestinal contents (e.g. perforated ulcer). In the latter case, superadded infection gradually occurs; *E. coli* and *Bacteroides* are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilatation and paralytic ileus.

Clinical features and management

In perforation, the onset is sudden with acute severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxæmia occurs.

When the peritonitis is secondary to inflammatory disease, the onset is less rapid with the initial features being those of the underlying disease.

Investigations should always include an erect chest X-ray. X-ray is used to detect free air under the diaphragm, and a

serum amylase to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should always be performed for diagnosis.

Peritonitis is treated surgically after adequate resuscitation with the re-establishment of a good urinary output. This includes insertion of a nasogastric tube, intravenous fluids and antibiotics. Surgery has a two-fold objective:

- Peritoneal lavage of the abdominal cavity
- Specific treatment of the underlying condition.

Complications

Any delay in treatment of peritonitis produces more profound toxemia and septicaemia which may lead to development of multiorgan failure (see p. 882). Local abscess formation can occur and should be suspected if a patient continues to remain unwell postoperatively with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic and can be localized and drained using ultrasound and CT scanning techniques.

Intestinal obstruction

Most intestinal obstruction is due to a mechanical block. Sometimes the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. Some causes of intestinal obstruction are shown in Table 6.30.

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination occurs in the distended stagnant bowel. In strangulation, the blood supply is impeded, leading to gangrene, perforation and peritonitis unless urgent treatment of the condition is undertaken.

Clinical features

The patient complains of abdominal colic, vomiting and constipation without passage of wind. In upper gut obstruction the vomiting is profuse but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant water-soluble gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately and is the investigation of choice.

Management

Initial management is by resuscitation with intravenous fluids (mainly isotonic saline with potassium) and decompression.

Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain and a rising white cell count require urgent scanning and possible exploratory laparotomy.

Laparotomy with removal of the obstruction will be necessary in some cases of small bowel obstruction. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g. those with Crohn's disease) may have recurrent episodes of incomplete intestinal obstruction that can be managed conservatively. In large bowel obstruction due to malignancy, colorectal stents are being used, followed by elective surgery. In critically ill patients, a defunctioning colostomy may be required. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink the bowel, but recurrent volvulus may require sigmoid resection.

Acute colonic pseudo-obstruction

It is now recognized that a clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. In more than 80% of cases, it complicates other clinical conditions, e.g.:

- Intra-abdominal trauma, pelvic spinal and femoral fractures
- Postoperatively (abdominal, pelvic, cardiothoracic, orthopaedic, neurosurgical)
- Intra-abdominal sepsis
- Pneumonia
- Metabolic (e.g. electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson's disease)
- Drugs – opiates (particularly after orthopaedic surgery), antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g. withdraw opiate analgesia) together with a trial of i.v. neostigmine therapy (Box 6.13). Patients should be monitored carefully and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

THE PERITONEUM

Structure and physiology

The peritoneal cavity is a closed sac lined by mesothelial cells, which produce surfactant that acts as a lubricant within the peritoneal cavity. The cavity contains <100 mL of serous fluid containing <30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the

parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation including histamine and eicosanoids and interact with T cells to generate an immune response.

The peritoneal-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity and the draining lymph nodes. B cells with a unique CD5+ are common. This defence system plays a major role in localizing peritoneal infection.

Disorders affecting the peritoneum

Conditions that can affect the peritoneum are shown in Table 6.31.

Peritonitis can be acute or chronic, as seen in tuberculosis. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections can also cause primary peritonitis (e.g. amoebiasis, candidiasis). Peritonitis is discussed further on page 300.

The peritoneum can be involved by secondary malignant deposits, and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A subphrenic abscess is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium and shoulder-tip pain. An erect chest X-ray shows gas under the diaphragm, impaired movement of the diaphragm on screening and a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter drainage inserted under CT or ultrasound guidance and antibiotics is highly successful therapy.

Ascites is associated with all diseases of the peritoneum. The fluid that collects is an exudate with a high protein content. It is also seen in liver disease. The mechanism,

causes and investigation of ascites are discussed in Chapter 7.

Retroperitoneal fibrosis (periaortitis)

This is a rare condition, in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is described on page 606.

Tuberculous peritonitis

This is the second most common form of abdominal TB.

Three subgroups can be identified: wet, dry and fibrous.

- In patients with the wet type, ascitic fluid should be examined for protein concentration (>20 g/L) and tubercle bacilli (rarely found).
- In the dry form, patients present with subacute intestinal obstruction which is due to tuberculous small bowel adhesions.
- In the fibrous form, patients present with abdominal pain, distension and ill-defined irregular tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node enlargement). A histological diagnosis is not always required before instituting treatment. In some patients careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

Treatment

Drug treatment is similar to that for pulmonary TB (see p. 842) and should be supervised by chest physicians who have experience in dealing with contacts.

INTRODUCTION

In many countries, alcohol is the major cause of liver disease, followed by hepatitis C virus infection. Hepatitis B virus is still a significant factor but widespread vaccination will reduce its prevalence. Non-alcoholic fatty liver disease is associated with the metabolic syndrome and is increasing in affluent countries. Health education and the improvement in public health should help to stop the spread of viral infections and reduce risk factors for metabolic syndrome.

Imaging techniques enable the liver, biliary tree and pancreas to be visualized with precision, resulting in earlier diagnosis. Therapeutic endoscopy, laparoscopic and minimally invasive surgery are now widely available for biliary tract and pancreatic disease. Finally, liver transplantation is established therapy for both acute and chronic liver disease.

THE LIVER

STRUCTURE OF THE LIVER AND BILIARY SYSTEM

The liver

The liver is the body's largest internal organ (1.2–1.5 kg) and is situated in the right hypochondrium. A functional division into the larger right lobe (containing caudate

and quadrate lobes) and the left lobe is made by the middle hepatic vein. The liver is further subdivided into eight segments (Fig. 7.1) by divisions of the right, middle and left hepatic veins. Each segment has its own portal pedicle, permitting individual segment resection at surgery.

The hepatic blood supply constitutes 25% of the resting cardiac output and is delivered via two main vessels, entering via the liver hilum (porta hepatis):

Figure 7.1 Segmental anatomy of the liver, showing the eight hepatic segments. I, caudate lobe; II–IV the left hemiliver; V–VIII the right hemiliver.

- **The hepatic artery**, a branch of the coeliac axis, supplies 25% of the hepatic blood flow. The hepatic artery autoregulates flow ensuring a constant total blood flow.
- **The portal vein** drains most of the gastrointestinal tract and the spleen. It supplies 75% of hepatic blood flow. The normal portal pressure is 5–8 mmHg; flow increases after meals.

The blood from these vessels is distributed to the segments and flows into the sinusoids via the portal tracts.

Blood leaves the sinusoids, entering branches of the hepatic vein which join into three main branches before entering the inferior vena cava.

The *caudate lobe* is an autonomous segment as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

Lymph, formed mainly in the perisinusoidal space, is collected in lymphatics which are present in the portal tracts. These small lymphatics enter larger vessels which eventually drain into the hepatic ducts.

The *acinus* is the functional hepatic unit. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles and bile ductules (Fig. 7.2). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3).

The *sinusoids* lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The subendothelial space between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents and stellate cells (see Fig. 7.23).

Stellate cells store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts) they are contractile and probably regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contractility. Activated stellate cells produce signal proteins for synthesis or inhibition of degradation of extracellular matrix components,

Figure 7.2 Diagram of an acinus. Zones 1, 2 and 3 represent areas supplied by blood, with zone 1 being best oxygenated. Zone 3 is supplied by blood remote from afferent vessels and is in the microcirculatory periphery of the acinus. The perivascular area (star-shaped green area around THV) is formed by the most peripheral parts of zone 3 of several adjacent acini and is the least well oxygenated. THV, terminal hepatic venule; PT, portal triad.

including collagen, as well as cytokines and chemotactic signals (see p. 328).

The biliary system

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which in turn enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts that leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct is formed at the junction of the cystic and common hepatic duct and is 8 mm in diameter or less, passing through the head of the pancreas, narrowing at its lower end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum most often through a common channel at the ampulla of Vater, which contains the muscular sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

FUNCTIONS OF THE LIVER

Protein metabolism (see also p. 197)

Synthesis and storage

The liver is the principal site of synthesis of all circulating proteins apart from γ -globulins (produced in the reticulo-endothelial system). The liver receives amino acids from

FURTHER READING

Dooley J, Lok A, Burroughs AK et al. Anatomy and function. In: *Sherlock's Diseases of the Liver and Biliary System*, 12th edn. London: Wiley-Blackwell; 2011.

the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates plasma levels. Plasma contains 60–80 g/L of protein, mainly albumin, globulin and fibrinogen.

Albumin has a half-life of 16–24 days, and 10–12 g are synthesized daily. Its main functions are to maintain the intravascular oncotic (colloid osmotic) pressure, and to transport water-insoluble substances such as bilirubin, hormones, fatty acids and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g. trauma with sepsis) and in diseases associated with an excessive loss (e.g. nephrotic syndrome, protein-losing enteropathy).

Transport or carrier proteins such as transferrin and caeruloplasmin, acute-phase and other proteins (e.g. α_1 -antitrypsin and α -fetoprotein) are also produced in the liver.

The liver also synthesizes all factors involved in coagulation (apart from one-third of factor VIII) – that is, fibrinogen, prothrombin, factors V, VII, IX, X and XIII, proteins C and S and antithrombin (see Ch. 8) as well as components of the complement system. The liver stores large amounts of vitamins, particularly A, D and B₁₂, and lesser amounts of others (vitamin K and folate), and also minerals – iron in ferritin and haemosiderin and copper.

Degradation (nitrogen excretion)

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is a major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

Carbohydrate metabolism

Glucose homeostasis and the maintenance of the blood sugar is a major function of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose release from breaking down glycogen (glycogenolysis) or by synthesizing new glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine) and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel as the body tissues adapt to a lower glucose requirement (see Ch. 5).

Lipid metabolism

Fats are insoluble in water and are transported in plasma as protein-lipid complexes (lipoproteins). These are discussed in detail on page 1005.

The liver has a major role in metabolizing of lipoproteins. It synthesizes very-low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin-cholesterol acyltransferase (LCAT), which catalyses the conversion of free cholesterol to cholesterol ester (see below). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs) which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 20.19).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol and incorporated into VLDLs. Oxidation or *de novo* synthesis of FFA occurs in the liver, depending on the availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-CoA mainly in the liver, intestine, adrenal

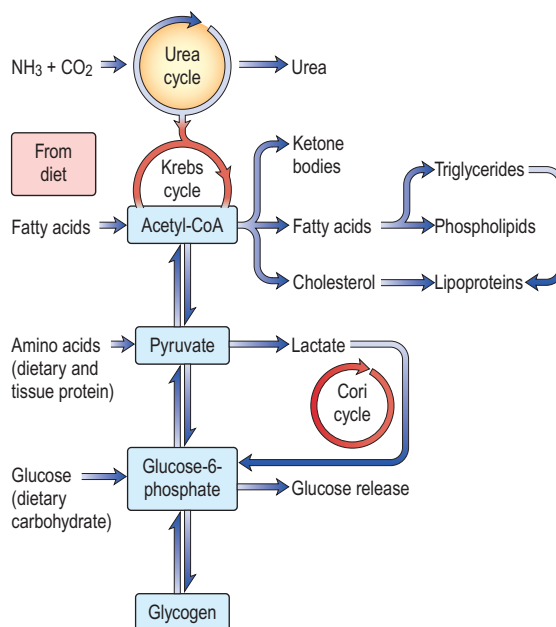

Figure 7.3 Interrelationships of protein, carbohydrate and lipid metabolism in the liver.

cortex and skin. It occurs either as free cholesterol or is esterified with fatty acids; this reaction is catalysed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g. target cells) seen in chronic liver disease. Phospholipids (e.g. lecithin) are synthesized in the liver. The complex interrelationships between protein, carbohydrate and fat metabolism are shown in Figure 7.3.

Formation of bile

Bile secretion and bile acid metabolism

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte – *bile salt-dependent* and *bile salt-independent* processes – each contributing about 230 mL/day. Another 150 mL daily is produced by epithelial cells of the bile ductules.

Bile formation requires uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins (sodium taurocholate co-transporting polypeptide (NTCP) and sodium independent organic anion transporting polypeptide 2 (OATP2), Fig. 7.4). This process is driven by Na⁺/K⁺-ATPase in the basolateral membranes. Intracellular transport across hepatocytes is partly through microtubules and partly by cytosol transport proteins.

Bile acids are also synthesized in hepatocytes from cholesterol, the rate-limiting step being those catalysed mainly by cholesterol-7 α -hydroxylase and the P450 enzymes (CYP7A1 and CYP8B1).

The bile acid receptor, farnesoid X, blocks bile acid formation from cholesterol and also regulates the transport proteins (NTCP, OATP2) that increase bile acid uptake by the liver. It is target for a new class of therapeutic drugs, farnesoid X receptor (FXR) agonists.

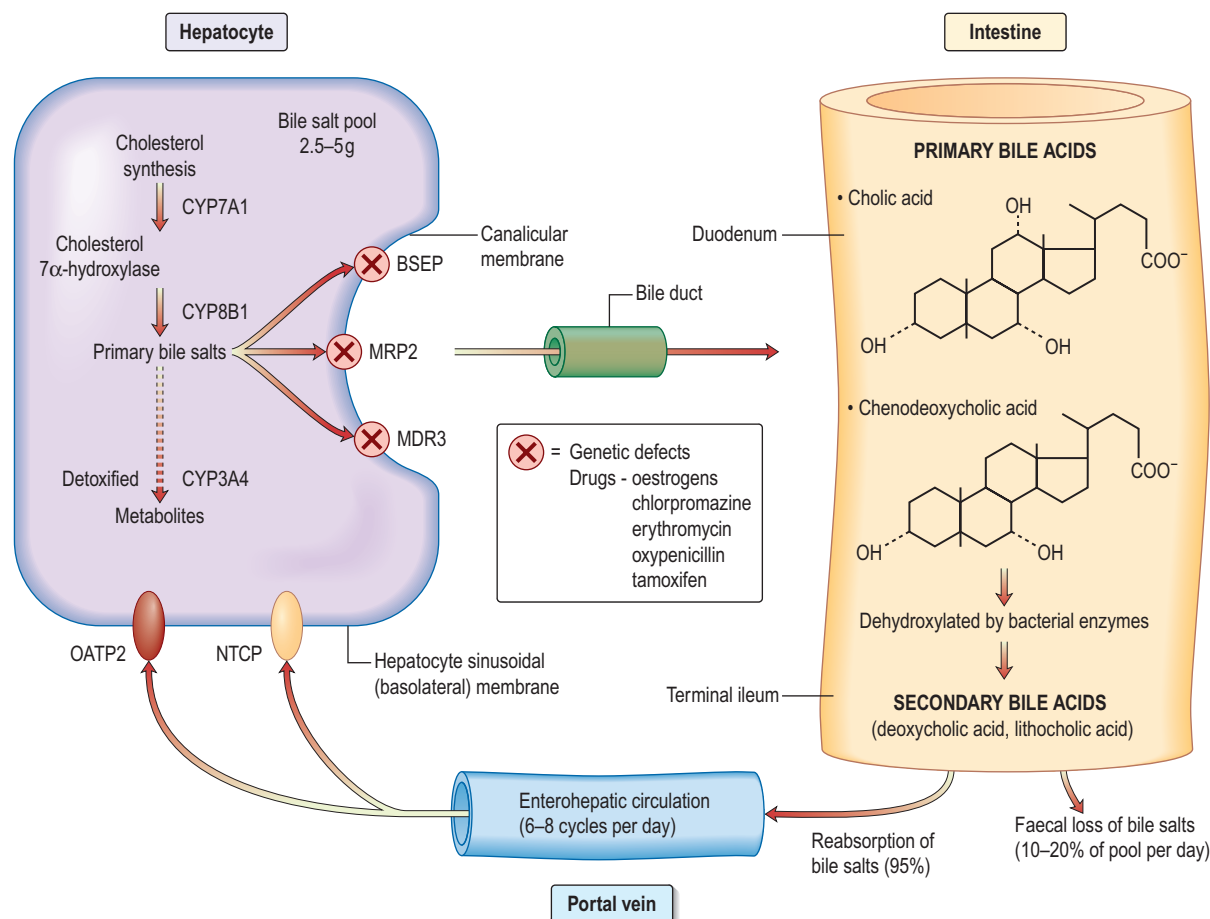

The canalicular membrane contains multispecific organic anion transporters, mainly ATPase dependent (ATP binding

cassette), the multidrug-resistance protein 2 (MRP2), multidrug resistance protein (MDR3) and the bile salt excretory pump (BSEP), which carry a broad range of compounds including bilirubin diglucuronide, glucuronidated and sulphated bile acids and other organic anions against a concentration gradient into the biliary canaliculus. Na⁺ and water follow the passage of bile salts by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process, water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and is inhibited by somatostatin. This involves several membrane proteins, including the Cl[−]/HCO₃[−] exchanger and the cystic fibrosis transmembrane conductance regulator which controls Cl[−] secretion, and water channels (aquaporins) in cholangiocyte membranes.

The bile acids are excreted into bile and then pass via the common bile duct into the duodenum. The two primary bile acids – cholic acid and chenodeoxycholic acid (Fig. 7.4) – are conjugated with glycine or taurine, which increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Figure 7.5 shows the enterohepatic circulation of bile acids.

The average total bile flow is 600 mL/day. When fasting half flows into the duodenum and half is diverted into the gall bladder. The gall bladder mucosa absorbs 80–90% of the water and electrolytes, but is impermeable to bile acids and cholesterol. Following a meal, the I cells of the duodenal

Figure 7.5 Recirculation of bile acids. The bile salt pool is relatively small and the entire pool recycles six to eight times via the enterohepatic circulation. Synthesis of new bile acids compensates for faecal loss.

mucosa secrete cholecystokinin, which, stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, allowing bile to enter the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules have both a hydrophilic and a hydrophobic end. In aqueous solutions they form micelles, with their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.

Bilirubin metabolism

Bilirubin is produced mainly from the breakdown of mature red cells by Kupffer cells in the liver and reticuloendothelial system; 15% of bilirubin is formed from catabolism of other haem-containing proteins, such as myoglobin, cytochromes and catalases.

Normally, 250–300 mg (425–510 mmol) of bilirubin are produced daily. The iron and globin are removed from haem and are reused. Biliverdin is formed from haem and then reduced to form bilirubin. The bilirubin produced is unconjugated and water-insoluble, due to internal hydrogen bonding, and is transported to the liver attached to albumin. Bilirubin dissociates from albumin and is taken up by hepatic cell membranes and transported to the endoplasmic reticulum by cytoplasmic proteins, where it is conjugated with glucuronic acid and excreted into bile. The microsomal enzyme, uridine diphosphoglucuronosyl transferase, catalyses the formation of bilirubin monoglucuronide and then diglucuronide. This conjugated bilirubin is water-soluble and is actively secreted into biliary canaliculi and excreted into the intestine within bile (Fig. 8.5). It is not absorbed from the small intestine because of its large molecular size. In the terminal ileum, bacterial enzymes hydrolyse the molecule, releasing free bilirubin which is then reduced to urobilinogen, some of which is excreted in the stools as stercobilinogen. The remainder is absorbed by the terminal ileum, passes to the liver via the enterohepatic circulation, and is re-excreted into bile. Urobilinogen bound to albumin enters the circulation and is excreted in urine via the kidneys. When hepatic excretion of conjugated bilirubin is impaired, a small amount is strongly bound to serum albumin and is not excreted by the kidneys; it accounts for the persistent hyperbilirubinaemia for a time after cholestasis has resolved.

Hormone and drug inactivation

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids and parathyroid hormone. It is also the prime target organ for many hormones (e.g. insulin). It is the major site for the metabolism of drugs (see p. 348) and alcohol (see p. 225). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.

Immunological function

The hepatic reticuloendothelial system contains many immunologically active cells. The liver acts as a 'sieve' for bacterial and other antigens carried to it by the portal vein from the gastrointestinal tract. These antigens are phagocytosed and degraded by the Kupffer cells, which have specific membrane receptors for ligands and are activated by several factors, such as infection. They are part of the innate immune system and secrete interleukins, tumour necrosis factor (TNF), collagenase and lysosomal hydrolases. Antigens are

degraded without the production of antibody, as there is very little lymphoid tissue and thus, they are prevented from reaching antibody-producing sites and thereby prevent generalized adverse immunological reactions. The reticuloendothelial system also plays a role in tissue repair, T and B lymphocyte interaction, and cytotoxic activity in disease processes. Following stimulation by, for example, endotoxin, the Kupffer cells release IL-6, IL-8 and TNF- α . These cytokines stimulate sinusoidal, stellate, and natural killer cells to release pro-inflammatory cytokines. The stimulated hepatocytes themselves express adhesion molecules and release IL-8, which is a potent neutrophil chemoattractant. Homing of mucosal lymphocytes (enterohepatic circulation) has been proposed. These exogenous leucocytes again release more cytokines – all damaging the function of the hepatocyte, including bile formation which leads to cholestasis. Cytokines also stimulate hepatic apoptosis.

INVESTIGATIONS

Investigative tests can be divided into:

■ Blood tests

- Liver 'function' tests:
 - serum albumin and bilirubin
 - prothrombin time (PT)
- Liver biochemistry:
 - serum aspartate (AST) and alanine aminotransferases (ALT) – reflecting hepatocellular damage
 - serum alkaline phosphatase (ALP), γ -glutamyl transpeptidase (γ GT) – reflecting cholestasis
 - total protein
- Viral markers
- Additional blood investigations; haematological, biochemical, immunological, markers of liver fibrosis and genetic analysis

■ Urine tests – for bilirubin and urobilinogen

■ Imaging techniques – to define gross anatomy

■ Liver biopsy – for histology.

Blood tests ordered for 'liver function' are usually processed by an automated multichannel analyser to produce serum levels of bilirubin, aminotransferases, alkaline phosphatase, γ -glutamyl transpeptidase (γ -GT) and total proteins. These routine tests are markers of liver damage, but not actual tests of 'function' *per se*. Subsequent investigations are often based on these tests.

Blood tests

Useful blood tests for certain liver diseases are shown in Table 7.1.

Liver function tests

Serum albumin

This is a marker of synthetic function and is useful to gauge the severity of chronic liver disease: a falling serum albumin is a bad prognostic sign. In acute liver disease initial albumin levels may be normal.

Prothrombin time (PT)

This is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly

Table 7.1 Useful blood and urine tests for certain liver diseases

Test	Disease
Anti-mitochondrial antibody	Primary biliary cirrhosis
Anti-nuclear, smooth muscle (actin), liver/kidney microsomal antibody	Autoimmune hepatitis
Raised serum immunoglobulins: IgG IgM	Autoimmune hepatitis Primary biliary cirrhosis
Viral markers	Hepatitis A, B, C, D, E and others
α -Fetoprotein	Hepatocellular carcinoma
Serum iron, transferrin saturation, serum ferritin	Hereditary haemochromatosis
Serum and urinary copper, serum caeruloplasmin	Wilson's disease
α_1 -Antitrypsin	Cirrhosis (\pm emphysema)
Anti-nuclear cytoplasmic antibodies	Primary sclerosing cholangitis
Markers of liver fibrosis	Non-alcoholic fatty liver disease Hepatitis C
Genetic analyses	e.g. <i>HFE</i> gene (hereditary haemochromatosis)

occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories depending upon the thromboplastin used in the assay. The International normalized ratio (INR) was developed to standardize anticoagulation with coumarin derivatives, but is very variable in liver disease, and causes large differences when included in prognostic scores for cirrhosis across different centres.

Liver biochemistry

Bilirubin

Serum bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Differentiation between conjugated or unconjugated bilirubin is only necessary in congenital disorders of bilirubin metabolism (see below) or to exclude haemolysis.

Aminotransferases

These enzymes (often referred to as transaminases) are contained in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

- **Aspartate aminotransferase (AST)** is primarily a mitochondrial enzyme (80%; 20% in cytoplasm) and is also present in heart, muscle, kidney and brain. High levels are seen in hepatic necrosis, myocardial infarction, muscle injury and congestive cardiac failure.
- **Alanine aminotransferase (ALT)** is a cytosol enzyme, more specific to the liver so that a rise only occurs with liver disease.

Alkaline phosphatase (ALP)

This is present in hepatic canalicular and sinusoidal membranes, but also in bone, intestine and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. In

clinical practice, if the γ -GT is also abnormal the ALP is presumed to come from the liver.

Serum ALP is raised in both intrahepatic and extrahepatic cholestatic disease of any cause, due to increased synthesis. In cholestatic jaundice, levels may be four to six times the normal limit. Raised levels also occur with hepatic infiltrations (e.g. metastases), and in cirrhosis, frequently in the absence of jaundice. The highest serum levels due to liver disease (>1000 IU/L) are seen with hepatic metastases and primary biliary cirrhosis.

γ -Glutamyl transpeptidase

This is a microsomal enzyme present in liver, but also in many tissues. Its activity can be induced by drugs such as phenytoin and by alcohol. If the ALP is normal, a raised serum γ -GT can be a useful guide to alcohol intake (see p. 1182). However, mild elevations of γ -GT are common, even with a small alcohol consumption and is also raised with fatty liver disease. It does not necessarily indicate liver disease if the other liver biochemical tests are normal. In cholestasis the γ -GT rises in parallel with the ALP as it has a similar pathway of excretion. This is also true of 5-nucleotidase, another microsomal enzyme that can be measured in blood.

Total proteins and globulin fraction

This measurement, is of little value. Serum albumin is discussed above. The proteins in the globulin fraction, raised in liver disease, can be separated by electrophoresis and is usually due to increased circulating immunoglobulins; it is polyclonal (see below).

Viral markers

Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

Additional blood investigations

Haematological

A full blood count may show anaemia. The red cells are often macrocytic and can have abnormal shapes – target cells and spur cells – owing to membrane abnormalities. Vitamin B₁₂ levels are normal or high, while folate levels are often low owing to poor dietary intake. Other changes are caused by the following:

- Bleeding produces a hypochromic, microcytic picture.
- Alcohol causes macrocytosis, sometimes with leucopenia and thrombocytopenia.
- Hypersplenism results in pancytopenia.
- Cholestasis can often produce abnormal-shaped cells, and also deficiency of vitamin K.
- Haemolysis may accompany acute liver failure and jaundice.
- Aplastic anaemia occurs in up to 2% of patients with acute viral hepatitis.
- A raised serum ferritin with transferrin saturation ($>60\%$) is seen in hereditary haemochromatosis.

Biochemical

- **α_1 -Antitrypsin.** A deficiency of this enzyme can produce cirrhosis.
- **α -Fetoprotein.** This is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in adults indicates hepatocellular carcinoma. Increased concentrations in pregnancy in blood and amniotic fluid suggest fetal neural tube

Tripodi A, Mannucci PM. The coagulopathy of chronic liver disease. *N Engl J Med* 2011; 365:147–156.

defects. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis, chronic liver disease and also in teratomas.

- Raised urinary copper, and low serum copper and caeruloplasmin in Wilson's disease (see p. 341).

Immunological tests

Serum immunoglobulins

Increased γ -globulins are thought to result from reduced phagocytosis by sinusoidal and Kupffer cells of the gut absorbed antigens. These antigens then stimulate antibody production in the spleen, lymph nodes and portal tract lymphoid and plasma cell infiltrates. In primary biliary cirrhosis, the predominant raised serum immunoglobulin is IgM, while in autoimmune hepatitis it is IgG. IgG4 is helpful in autoimmune pancreatitis.

Serum autoantibodies

- **Anti-mitochondrial antibody (AMA)** in serum is found in over 95% of patients with primary biliary cirrhosis (PBC) (p. 338). Several different AMA subtypes are described, depending on their antigen specificity, and are also found in autoimmune hepatitis and other autoimmune diseases. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. M2 subtype is specific for PBC.
- **Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies** can be found in serum, often in high titre, in patients with autoimmune hepatitis. These serum antibodies can also be found in other autoimmune conditions and other liver diseases.
- **Anti-nuclear cytoplasmic antibodies (ANCA)** can be found in serum of patients with primary sclerosing cholangitis.

Markers of liver fibrosis

Fibrosis plays a key role in the outcome of many chronic liver diseases. Blood tests are being used to detect and quantify fibrosis and thereby decrease the need of liver biopsy. To date, these have been developed mainly for chronic hepatitis C, and less so for non-alcoholic fatty liver disease.

Commercial tests are available which measure α_2 -macroglobulin, α_2 -haptoglobin, γ -globulin, apoprotein A₁, γ -GT and total bilirubin. Some are based on age, blood ferritin, glucose, AST, ALT, platelet count and bodyweight. These results are formulated to determine a fibrosis index. The indices are sensitive and specific (>90%) for the absence of fibrosis, and have 80% sensitivity and specificity for severe fibrosis, but cannot reliably assess the severity of fibrosis.

Markers of matrix deposition include procollagen I and III peptide and type IV collagen. **Markers of matrix degradation**, e.g. matrix metalloproteinase (MMP) 2 and 9, and tissue inhibitors of metalloproteinases (TIMPS), e.g. TIMP1 and 2, all are being used as markers of fibrosis.

AST to platelet ratio index (APRI) is less accurate than the tests mentioned above.

Genetic analysis

These tests are performed routinely for haemochromatosis (HFE gene) and for α_1 -antitrypsin deficiency. Markers are also available for the most frequent abnormal genes in Wilson's disease (see p. 341).

Urine tests

Dipstick tests are available for bilirubin and urobilinogen. Bilirubinuria is due to the presence of conjugated (soluble) bilirubin, is found in patients with jaundice due to hepatobiliary

disease, but is absent if unconjugated bilirubin is the major cause of jaundice. The presence of urobilinogen in urine in practice is of little value but suggests haemolysis or hepatic dysfunction.

Imaging techniques

Ultrasound examination

This is a non-invasive, safe and relatively cheap technique. It involves the analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein and other structures in the abdomen can be visualized. Abdominal ultrasound is useful in:

- a jaundiced patient (p. 312)
- hepatomegaly/splenomegaly
- the detection of gallstones (Fig. 7.6)
- focal liver disease – lesions >1 cm
- general parenchymal liver disease
- assessing portal and hepatic vein patency
- lymph node enlargement.

Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance.

Colour Doppler ultrasound will demonstrate vascularity within a lesion and the direction of portal and hepatic vein blood flow (Fig. 7.7).

Ultrasound contrast agents, mostly based on production of microbubbles within flowing blood, enhance the detection of vascularity, allowing the detection of abnormal circulation within liver nodules, giving a more specific diagnosis of hepatocellular carcinoma.

Hepatic stiffness (transient elastography). Using an ultrasound transducer, a vibration of low frequency and amplitude is passed through the liver, the velocity of which correlates with hepatic stiffness. Stiffness (measured in kPa) increases with worsening liver fibrosis (sensitivity and specificity 80–95% compared to liver biopsy). It is not accurate enough to diagnose cirrhosis, and less accurate for less severe fibrosis. It cannot be used in the presence of ascites and morbid obesity, and it is affected by inflammatory tissue

Figure 7.6 Gall bladder ultrasound with multiple echogenic gallstones causing well-defined acoustic shadowing. (1) gall bladder; (2) gallstones; (3) echogenic shadow.

Figure 7.7 Doppler signal of the portal vein is shown as a trace and the visual counterpart in red showing patency and forward flow into the liver.

and congestion. Acoustic radiation force impulse is incorporated into standard B mode ultrasonography and has similar physical principles to transient elastography.

Endoscopic ultrasound (EUS)

A small high-frequency ultrasound probe is incorporated into the tip of an endoscope and placed by direct vision into the lumen of the gut. The close proximity of the probe to the pancreas and biliary tree permits high-resolution ultrasound imaging. It allows accurate staging of small, potentially operable, pancreatic tumours and offers a less invasive method for bile duct imaging. It has a high accuracy in detection of small neuroendocrine tumours of the pancreas. EUS-guided fine-needle aspiration of tumours provides cytological/histological tissue for confirmation of malignancy. EUS is also used to place transmural tubes to drain pancreatic and peripancreatic fluid collections.

Computed tomography (CT) examination

CT during or immediately after i.v. contrast shows both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (Fig. 7.8). Retrospective analysis of data allows multiple overlapping slices to be obtained with no increase in the radiation dose, providing excellent visualization of the size, shape and density of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatis. Multi-planar and three-dimensional reconstruction in the arterial phase can create a CT angiogram, often making formal invasive angiography unnecessary. CT also provides guidance for biopsy. It has advantages over US in detecting calcification and is useful in obese subjects, although US is usually the imaging modality used first to investigate liver disease.

Magnetic resonance imaging (MRI)

MRI produces cross-sectional images in any plane within the body and does not involve radiation. MRI is the most sensitive investigation of focal liver disease. Diffuse liver disease alters the T1 and T2 characteristics. Other fat-suppression modes such as STIR allow good differentiation between haemangiomas and other lesions. Contrast agents such as intravenous gadolinium, which allow further characterization of lesions, are suitable for those with iodine allergy, and provide angiography and venography of the splanchnic circulation. This has superseded direct arteriography.

a Unenhanced.

b Arterial phase (note high-density contrast in the aorta).

c Portal venous phase scan through the right lobe of the liver.

Figure 7.8 Use of contrast-enhanced spiral CT. There is an irregular mass (arrow) in the posterior aspect of the right lobe of the liver which is only well seen on the early arterial phase enhanced scan.

Magnetic resonance cholangiopancreatography (MRCP)

This technique involves the manipulation of data acquired by MRI. A heavily T2-weighted sequence enhances visualization of the 'water-filled' bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) ERCP (see below), and is usually the next test if a biliary abnormality is present on US examination.

Plain X-rays of the abdomen

These are rarely requested but may show:

- gallstones – 10% contain enough calcium to be seen
- air in the biliary tree owing to its recent instrumentation, surgery or to a fistula between the intestine and the gall bladder
- pancreatic calcification
- rarely, calcification of the gall bladder (porcelain gall bladder).

Radionuclide imaging – scintiscanning

In a ^{99m}Tc -IODIDA scan, technetium-labelled iododiethyl IDA is taken up by the hepatocytes and excreted rapidly into the biliary system. Its main uses are in the diagnosis of:

- acute cholecystitis
- jaundice due to either biliary atresia or hepatitis in the neonatal period.

Endoscopy

Upper GI endoscopy is used for diagnosis and treatment of varices, detection of portal hypertensive gastropathy, and for associated lesions such as peptic ulcers. Colonoscopy may show portal hypertensive colopathy. Capsule endoscopy can identify small intestinal varices.

Endoscopic retrograde cholangiopancreatography (ERCP)

This technique outlines the biliary and pancreatic ducts. It involves the passage of an endoscope into the second part of the duodenum and cannulation of the ampulla. Contrast is injected into both systems and the patient is screened radiologically. Contrast medium with a low iodine content of 1.5 mg/mL is used for the common bile duct so that gallstones are not obscured; a higher iodine content of 2.8 mg/mL is used for the pancreatic duct. Diagnostic ERCP has been replaced by MRCP in nearly all clinical settings. Therapeutic ERCP involves the following:

- Common bile duct stones can be removed after performing a diathermy cut of the sphincter to facilitate their withdrawal. Sphincterotomy has a morbidity rate of 3–5%: acute pancreatitis is the commonest, severe haemorrhage is rare. There is an overall mortality of 0.4%.
- The biliary system can be drained by passing a tube (stent) through an obstruction, or placement of a nasobiliary drain.
- Brachytherapy can be administered after placement at ERCP for therapy of cholangiocarcinoma.

A raised serum amylase is often seen following ERCP and pancreatitis is the most common complication. Cholangitis with or without septicaemia is also seen, and broad-spectrum antibiotics (e.g. 500 mg ciprofloxacin \times 2) should be given prophylactically to all patients with suspected biliary obstruction, or a history of cholangitis.

Percutaneous transhepatic cholangiography (PTC)

Under a local anaesthetic, a fine flexible needle is passed into the liver. Contrast is injected slowly until a biliary radicle is identified and then further contrast is injected to outline the whole of the biliary tree. In patients with dilated ducts, the success rate is near 100%. PTC is performed if ERCP fails or is likely to be technically difficult.

In difficult cases ERCP and PTC are sometimes combined, PTC showing the biliary anatomy above the obstruction, with ERCP showing the more distal anatomy. If an obstruction in the bile ducts is seen, a bypass stent can usually be inserted with or without temporary external biliary drainage. Contraindications of PTC are as for liver biopsy (see below). The main complications are bleeding and cholangitis with septicaemia, and prophylactic antibiotics should be given as for ERCP.

Angiography

This is performed by selective catheterization of the coeliac axis and hepatic artery. It outlines the hepatic vasculature and the abnormal vasculature of hepatic tumours, but spiral CT and magnetic resonance scanning have replaced diagnostic angiography. The portal vein can be demonstrated with increased definition using subtraction techniques replacing splenoportography (by direct splenic puncture).

In **digital vascular imaging** (DVI), contrast given intravenously or intra-arterially can be detected in the portal system using computerized subtraction analysis.

Hepatic venous cannulation allows abnormal hepatic veins to be diagnosed in patients with Budd–Chiari syndrome and is also used to measure portal pressure indirectly. There is a 1:1 relationship of occluded (by balloon) hepatic venous pressure, with portal pressure in patients with alcoholic or viral-related cirrhosis. The height of portal pressure has prognostic value for survival in cirrhosis, and a difference of the occluded minus the free hepatic venous pressure (hepatic venous pressure gradient HVPG) of 20% or more from baseline values or <12 mmHg, has been associated with protection from rebleeding, and prevention of other complications of cirrhosis.

Retrograde CO₂ portography is used when there is doubt about portal vein patency and can be combined with transjugular biopsy and hepatic venous pressure measurement.

Liver biopsy (Practical Box 7.1)

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease. Liver biopsy can be performed on a day-case basis. The indications and contraindications are shown in [Table 7.2](#). The mortality rate is less than 0.02% when performed by experienced operators.

Liver biopsy guided by ultrasound or CT is performed when specific lesions need to be biopsied. Laparoscopy with guided liver biopsy is performed through a small incision in the abdominal wall under local anaesthesia (general anaesthesia is preferred in some centres). A transjugular approach is used when liver histology is essential for management but coagulation abnormalities or ascites prevent the percutaneous approach.

Most complications of liver biopsy occur within 24 h (usually in the first 2 h). They are often minor and include abdominal or shoulder pain which settles with analgesics. Minor intraperitoneal bleeding can occur, but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia and transient septicaemia. Haemobilia produces

Practical Box 7.1

Needle biopsy of the liver

This should be performed only by experienced doctors and with sterile precautions. Patient consent must be obtained following explanation of the procedure.

- The patient's coagulation status (prothrombin time, platelets) is checked.
- The patient's blood group is checked and serum saved for crossmatching.
- The patient lies on their back at the edge of the couch.
- Ultrasound examination can be used to confirm liver margins and position of the gall bladder. Alternatively, the liver margins are delineated using percussion.
- Local anaesthetic is injected at the point of maximum dullness in the mid-axillary line through the intercostal space during expiration. Anaesthetic (1% lidocaine, approximately 5 mL) should be injected down to the liver capsule.
- A tiny cut is made in the skin with a scalpel blade.
- A special needle (Menghini, Trucut or Surecut) is used to obtain the liver biopsy while the patient holds his breath in expiration.
- The biopsy is laid on filter paper and placed in 10% formalin. If a culture of the biopsy is required it should be placed in a sterile pot.
- The patient should be observed, with pulse and blood pressure measurements taken regularly for at least 6 h.

Table 7.2 Indications and contraindications for liver biopsy

Indications

Liver disease
Unexplained hepatomegaly
Some cases of jaundice
Persistently abnormal liver biochemistry
Occasionally in acute hepatitis
Chronic hepatitis
Cirrhosis
Drug-related liver disease
Infiltrations
Tumours: primary or secondary
Infections (e.g. tuberculosis)
Storage disease (e.g. glycogen storage)
Pyrexia of unknown origin

Usual contraindications to percutaneous needle biopsy

Uncooperative patient
Prolonged prothrombin time (by >3 s)
Platelets <80 × 10⁹/L
Ascites
Extrahepatic cholestasis

biliary colic, jaundice and melaena within 3 days of the biopsy.

SYMPTOMS OF LIVER DISEASE

Acute liver disease

This may be asymptomatic and anicteric. Symptomatic disease, which is often viral, produces generalized symptoms of malaise, anorexia and fever. Jaundice may appear as the illness progresses.

Chronic liver disease

Patients may be asymptomatic or complain of nonspecific symptoms, particularly fatigue. Specific symptoms include:

- Right hypochondrial pain due to liver distension
- Abdominal distension due to ascites
- Ankle swelling due to fluid retention

- Haematemesis and melaena from gastrointestinal haemorrhage
- Pruritus due to cholestasis – this is often an early symptom of primary biliary cirrhosis
- Breast swelling (gynaecomastia), loss of libido and amenorrhoea due to endocrine dysfunction
- Confusion and drowsiness due to neuropsychiatric complications (portosystemic encephalopathy).

SIGNS OF LIVER DISEASE

Acute liver disease

There may be few signs apart from jaundice and an enlarged liver. Jaundice is a yellow coloration of the skin and mucous membranes and is best seen in the conjunctivae and sclerae. In the cholestatic phase of the illness, pale stools and dark urine are present. Spider naevi and palmar erythema usually indicate chronic disease but they can occur in severe acute disease.

Chronic liver disease

The physical signs are shown in [Figure 7.9](#). However, the physical examination is sometimes normal in patients with advanced chronic liver disease.

The skin

The chest and upper body may show *spider naevi*. These are telangiectases that consist of a central arteriole with radiating small vessels. They are found in the distribution of the superior vena cava (i.e. above the nipple line) – commonly more than five is taken as diagnostic. They are also found in pregnancy. In haemochromatosis the skin may have a slate-grey appearance.

The hands may show *palmar erythema*, which is a nonspecific change indicative of a hyperdynamic circulation; it is also seen in pregnancy, thyrotoxicosis or rheumatoid arthritis. Clubbing occasionally occurs, and a Dupuytren's contracture is often seen in alcoholic cirrhosis.

Xanthomas (cholesterol deposits) are seen in the palmar creases or above the eyes in primary biliary cirrhosis.

The abdomen

Initial hepatomegaly will be followed by a small liver in well-established cirrhosis. Splenomegaly is seen with portal hypertension.

The endocrine system

Gynaecomastia (occasionally unilateral) and testicular atrophy may be found in males. The cause of gynaecomastia is complex, but it is probably related to altered oestrogen metabolism or to treatment with spironolactone.

In decompensated cirrhosis, additional signs that can be seen are shown in [Figure 7.9](#).

JAUNDICE

Jaundice (icterus) is detectable clinically when the serum bilirubin is >50 µmol/L (3 mg/dL). It is useful to divide jaundice into:

- Haemolytic jaundice – increased bilirubin load for the liver cells
- Congenital hyperbilirubinaemias – defects in conjugation
- Cholestatic jaundice, including hepatocellular (parenchymal) liver disease and large duct obstruction.

Figure 7.9 Physical signs in chronic liver disease.

Haemolytic jaundice

The increased breakdown of red cells (see p. 375) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68–102 $\mu\text{mol/L}$ or 4–6 mg/dL) as normal liver function can easily handle the increased bilirubin derived from excess haemolysis. Unconjugated bilirubin is not water-soluble and therefore does not pass into urine; hence the term 'acholuric jaundice'. Urinary urobilinogen is increased.

The causes of haemolytic jaundice are those of haemolytic anaemia (p. 375). The clinical features depend on the cause; anaemia, jaundice, splenomegaly, gallstones and leg ulcers may be seen.

Investigations show features of haemolysis (p. 375). The level of unconjugated bilirubin is raised but the serum ALP, transferases and albumin are normal. Serum haptoglobulins are low. The differential diagnosis is from other forms of jaundice.

Congenital hyperbilirubinaemias (non-haemolytic)

Unconjugated

Gilbert's syndrome

This is the most common familial hyperbilirubinaemia and affects 2–7% of the population. It is asymptomatic and is usually detected as an incidental finding of a slightly raised bilirubin (17–102 $\mu\text{mol/L}$ or 1–6 mg/dL) on a routine check. All the other liver biochemistry is normal and there are no signs of liver disease. There is a family history of jaundice in 5–15% of patients. Hepatic glucuronidation is approximately 30% of normal, resulting in an increased proportion of bilirubin monoglucuronide in bile. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity, the enzyme that conjugates bilirubin with glucuronic acid. Mutations occur in the gene (*HUG-Br1*) encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream 5' promoter element. This

abnormality appears to be necessary for the syndrome, but is not in itself sufficient for the clinical manifestation (phenotypic expression).

Establishing this diagnosis is necessary to inform the patient that this is not a serious disease and to prevent unnecessary investigations. The raised unconjugated bilirubin is diagnostic and rises on fasting and during a mild illness. The reticulocyte count is normal, excluding haemolysis, and no treatment is necessary.

Crigler-Najjar syndrome

This is very rare. Only patients with type II (autosomal dominant) with a decrease rather than absence (type I – autosomal recessive) of UDP-glucuronosyl transferase can survive into adult life. Mutation of the *HUG-Br1* gene for UDP-glucuronosyl transferase has been demonstrated in the coding region. Liver histology is normal. Transplantation is the only effective treatment.

Conjugated

Dubin-Johnson (autosomal recessive) and **Rotor syndromes** are due to defects in hepatic bilirubin handling. The prognosis is good in both. In the Dubin-Johnson syndrome there are mutations in both *MRP2* (p. 305) transporter genes; the liver is black owing to melanin deposition.

Benign recurrent intrahepatic cholestasis

This is rare and presents in early adulthood. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea and weight loss develop. Serum $\gamma\text{-GT}$ is normal. The gene has been mapped to the *FIC1* locus, but the precise relation to cholestasis is unclear. It may be associated with intrahepatic cholestasis of pregnancy (p. 346).

Progressive familial intrahepatic cholestasis (PFIC) syndromes

This is a heterogeneous group of conditions defined by defective secretion of bile acids (see Figs 7.4 and 7.29). They are autosomal recessive. In *type 1* (PFIC1), with cholestasis in the first weeks of life, the $\gamma\text{-GT}$ is normal. The gene is on the familial intrahepatic cholestasis-1 gene (*FIC1*) locus, and has been mapped to a region encoding P type ATPases (ATP8B1) on chromosome 18q21. *Type 2* (PFIC2) has been mapped to the bile salt export pump gene (*BSEP*, also called *ABCB1*). The protein is located in the canalicular domain of the hepatocyte plasma membrane. The phenotypic expression frequently is a nonspecific giant cell hepatitis progressing to cholestasis – in both types, the $\gamma\text{-GT}$ is normal. *Type 3* is due to a multidrug resistance protein 3-P-glycoprotein *PGY3* (*MDR-3*) gene mutation (also called *ABCB4* gene) leading to deficient canalicular phosphatidylcholine transport and thus toxic bile acids causing liver damage, which can lead to cirrhosis. Liver transplantation is the only cure for these syndromes.

Cholestatic jaundice (acquired)

This can be divided into extrahepatic and intrahepatic cholestasis. The causes are shown in Figure 7.10.

- Extrahepatic cholestasis is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.
- Intrahepatic cholestasis occurs owing to failure of bile secretion. A number of cellular mechanisms in cholestasis have been described in animal models, including inhibition of the $\text{Na}^+/\text{K}^+\text{-ATPase}$ in the

Figure 7.10 Causes of jaundice.

basolateral membranes, decreased fluidity of the sinusoidal plasma membrane, disruption of the microfilaments responsible for canalicular tone, and damage to the tight junctions. In addition, inflammatory change in ductular cells interferes with bile flow.

Clinically in both types, there is jaundice with pale stools and dark urine, and the serum bilirubin is conjugated. However, intrahepatic and extrahepatic cholestatic jaundice must be differentiated as their clinical management is entirely different.

Differential diagnosis of jaundice

The history often gives a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people. For example, a young person is more likely to have hepatitis, so questions should be asked about drug and alcohol use, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction by gallstones, and sometimes with an enlarged liver there is pain resulting from distension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered.

- **Country of origin.** The incidence of hepatitis B virus (HBV) infection is increased in many parts of the world (p. 318).
- **Duration of illness.** A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests a hepatitis.
- **Recent outbreak of jaundice.** An outbreak in the community suggests hepatitis A virus (HAV).
- **Recent consumption of shellfish.** This suggests HAV infection.
- **Intravenous drug use, or recent injections or tattoos.** These all increase the chance of HBV and hepatitis C virus (HCV) infection.
- **Men having sex with men.** This increases the chance of HBV infection.
- **Female sex workers.** This increases the chance of HBV infection.
- **Blood transfusion or infusion of pooled blood products.** Increased risk of HBV and HCV. In developed countries all donors are screened for HBV and HCV.

- **Alcohol consumption.** A history of drinking habits should be taken, although many patients often understate their consumption.
- **Drugs taken (particularly in the previous 2–3 months).** Many drugs cause jaundice (see p. 348).
- **Travel.** Certain areas have a high risk of HAV infection as well as hepatitis E (HEV) infection (this has a high mortality in pregnancy), but HAV is common in the UK.
- **A recent anaesthetic.** Halothane (named patient basis only in UK) and occasionally isoflurane, and sevoflurane may cause jaundice, particularly in those already sensitive to halogenated anaesthetics. The risk with desflurane appears remote.
- **Family history.** Patients with, for example, Gilbert's disease may have family members who get recurrent jaundice.
- **Recent surgery** on the biliary tract or for carcinoma.
- **Environment.** People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis, hepatitis E and exposure to chemicals.
- **Fevers or rigors.** These are suggestive of cholangitis or possibly a liver abscess.

Clinical features

The signs of acute and chronic liver disease should be looked for (p. 312). Certain additional signs may be helpful:

- **Hepatomegaly.** A smooth tender liver is seen in hepatitis and with extrahepatic obstruction, but a knobby irregular liver suggests metastases. Causes of hepatomegaly are shown in Table 7.3.
- **Splenomegaly.** This indicates portal hypertension in patients when signs of chronic liver disease are present. The spleen can also be 'tipped' occasionally in viral hepatitis.
- **Ascites.** This is found in cirrhosis but can also be due to carcinoma (particularly ovarian) and many other causes (see Table 7.14).

A palpable gall bladder occurs with a carcinoma of the pancreas obstructing the bile duct. Generalized lymphadenopathy suggests a lymphoma.

Cold sores are seen with a herpes simplex virus hepatitis.

Investigations

Jaundice is not itself a diagnosis and the cause should always be sought. The two most useful tests are the viral markers for HAV, HBV and HCV (in high-risk groups), with an ultrasound examination. Liver biochemistry confirms the jaundice and may help in the diagnosis.

An ultrasound examination should always be performed to exclude an extrahepatic obstruction, and to diagnose any features compatible with chronic liver disease except when hepatitis A is strongly suspected in a young patient. Ultrasound will demonstrate:

- the size of the bile ducts, which are dilated in extrahepatic obstruction (Fig. 7.11)
- the level of the obstruction

Heart failure
Constrictive pericarditis
Hepatic vein occlusion

Biliary obstruction (particularly extrahepatic)

- the cause of the obstruction in virtually all patients with tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made by fine-needle aspiration cytology (sensitivity approximately 60%) or by needle biopsy using a spring-loaded device (sensitivity approximately 90%).

A flow diagram for the general investigation of the jaundiced patient is shown in Figure 7.12.

Liver biochemistry

In hepatitis, serum AST and ALT tend to be high early in the disease with only a small rise in serum ALP. Conversely, in extrahepatic obstruction the ALP is high with a smaller rise in aminotransferases. However, these findings cannot be relied upon alone to make a diagnosis in an individual case. The prothrombin time (PT) is often prolonged in longstanding liver disease, and the serum albumin is also low.

Haematological tests

In haemolytic jaundice the bilirubin is raised and the other liver biochemistry is normal. A raised white cell count may indicate infection (e.g. cholangitis). A leucopenia often occurs in viral hepatitis, while abnormal mononuclear cells suggest infectious mononucleosis and a Monospot test should be performed.

Figure 7.11 Liver ultrasound showing (a) dilated intrahepatic bile ducts (arrow), (b) common bile duct (arrow). The normal bile duct measures 6 mm at the porta hepatis.

Other blood tests

These include tests to confirm the presence of specific causes of acute or chronic liver disease, e.g. antimitochondrial antibody (AMA) for PBC. HIV status should be established.

HEPATITIS

Acute parenchymal liver damage can be caused by many agents (Fig. 7.13).

Chronic hepatitis is defined as any hepatitis lasting for 6 months or longer and is classified according to the aetiology (Table 7.4). Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis and hepatocellular carcinoma worldwide.

Acute hepatitis

Pathology

Although some histological features are suggestive of the aetiological factor, most changes are similar whatever the cause. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation), undergo necrosis (becoming shrunken, containing eosinophilic Councilman bodies) and are rapidly removed. The distribution of these changes may vary with aetiology, but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals even when affected by the same agent: at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end there is multiacinar necrosis involving a substantial part of the liver (massive hepatic necrosis) resulting in fulminant hepatic failure. Between these extremes there is limited confluent necrosis with collapse of the reticulin framework

resulting in linking (bridging) between the central veins, the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable, but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis that is due to alcohol or certain drugs.

Chronic hepatitis

Pathology

Chronic inflammatory cell infiltrates comprising lymphocytes, plasma cells and sometimes lymphoid follicles are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:

- loss of definition of the portal/periportal limiting plate – interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis and focal inflammation
- confluent necrosis
- fibrosis which may be mild, bridging (across portal tracts) or severe cirrhosis.

The overall severity of the hepatitis is judged by the degree of the hepatitis and inflammation (grading) and the severity of the fibrosis or cirrhosis (staging). In chronic viral hepatitis there are various scoring systems. For example, the *Knodell Scoring System* (histological activity index) uses the sum of four factors (periportal or bridging necrosis, intralobular degeneration and focal necrosis, portal inflammation and fibrosis). The *Ishak score* stages fibrosis from 0 (none) to 6 (cirrhosis). The METAVIR system has four stages. Scoring systems are used for drug trials and for assessing progression of disease, but are descriptions of architectural changes and not quantitative measures of fibrosis.

VIRAL HEPATITIS

The differing features of the common forms of viral hepatitis are summarized in Table 7.5.

Hepatitis A

Epidemiology

Hepatitis A is the most common viral hepatitis occurring worldwide, often in epidemics. The disease is commonly seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from the ingestion of contaminated food or water (e.g. shellfish). Overcrowding and poor sanitation facilitate spread. There is no carrier state. In the UK it is a notifiable disease.

Hepatitis A virus (HAV)

HAV is a picornavirus, having the structure shown in Figure 7.14. It has a single serotype as only one epitope is immunodominant. It replicates in the liver, is excreted in bile and then excreted in the faeces for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

Clinical features

The viraemia causes the patient to feel unwell with nonspecific symptoms that include nausea, anorexia and a distaste

Table 7.5 Some features of viral hepatitis

	A	B	C	D	E

^aChronic hepatitis in immunosuppressed patients.**a HAV virion****b HAV genome**

Figure 7.14 (a) The hepatitis A (HAV) virion consists of four polypeptides (VP1–VP4) which form a tight protein shell, or capsid, containing the RNA. The major antigenic component is associated with VP1.

(b) Arrangement of HAV genome.

for cigarettes. Many recover at this stage and remain anicteric.

After 1 or 2 weeks, some patients become jaundiced and symptoms often improve. Persistence of nausea, vomiting or any mental confusion warrants assessment in hospital. As the jaundice deepens, the urine becomes dark and the stools pale owing to intrahepatic cholestasis. The liver is moderately enlarged and the spleen is palpable in about 10% of patients. Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter the jaundice lessens and in the majority of cases the illness is over within 3–6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis and acute kidney injury. A biphasic illness occasionally occurs, with the return of jaundice. Rarely the disease may be very severe with fulminant hepatitis, liver coma and death. The typical sequence of events after HAV exposure is shown in [Figure 7.15](#).

Investigations**Liver biochemistry**

Prodromal stage: the serum bilirubin is usually normal. However, there is bilirubinuria and increased urinary urobilinogen. A raised serum AST or ALT, which can sometimes be very high, precedes the jaundice.

Icteric stage: the serum bilirubin reflects the level of jaundice. Serum AST reaches a maximum 1–2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.

After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests

There is leucopenia with a relative lymphocytosis. Very rarely there is a Coombs'-positive haemolytic anaemia or an associated aplastic anaemia. The prothrombin time (PT) is prolonged in severe cases. The erythrocyte sedimentation rate (ESR) is raised.

SIGNIFICANT WEBSITE

Viral hepatitis:
http://www.easl.eu/_clinical-practice-guideline

Figure 7.15 HAV: sequence of events after exposure.

Viral markers: antibodies to HAV

IgG antibodies are common in the general population over the age of 50 years, but an anti-HAV IgM means an acute infection. In areas of high prevalence most children have antibodies by the age of 3 years following asymptomatic infection.

Other tests

Further tests are not necessary in the presence of an IgM antibody, but liver biochemistry must be followed to establish a return to normal levels.

Differential diagnosis is from all other causes of jaundice, but in particular from other types of viral and drug-induced hepatitis.

Course and prognosis

The prognosis is excellent, with most patients making a complete recovery. The mortality in young adults is 0.1% but it increases with age. Death is due to fulminant hepatic necrosis. During convalescence, 5–15% of patients may have relapse of the hepatitis but this settles spontaneously. Occasionally, a more severe jaundice with cholestasis will run a prolonged course of 7–20 weeks and is called 'cholestatic viral hepatitis'.

There is no reason to stop alcohol consumption other than for the few weeks when the patient is ill. Patients may complain of debility for several months following resolution of the symptoms and biochemical parameters. This is known as the post-hepatitis syndrome; it is a functional illness. Treatment is by reassurance. HAV hepatitis never progresses to chronic liver disease.

Treatment

There is no specific treatment, and rest and dietary measures are unhelpful. Corticosteroids have no benefit. Admission to hospital is not usually necessary.

Prevention and prophylaxis

Control of hepatitis depends on good hygiene. The virus is resistant to chlorination but is killed by boiling water for 10 min.

Active immunization

A formaldehyde-inactivated HAV vaccine is given to people travelling frequently to endemic areas, patients with chronic liver disease, people with haemophilia, and workers

in frequent contact with hepatitis cases (e.g. in residential institutions for patients with learning difficulties). Community outbreaks can be interrupted by vaccination. A single dose produces antibodies that persist for at least 1 year, with immunity lasting beyond 10 years. This obviates the need for a booster injection in healthy individuals. Universal vaccination has been suggested.

Passive immunization

Normal human immunoglobulin (0.02 mL/kg i.m.) is used if exposure to HAV is <2 weeks. HAV vaccine should also be given.

Hepatitis B

Epidemiology

The hepatitis B virus (HBV) is present worldwide with an estimated 360 million carriers. The UK and the USA have a low carrier rate (0.5–2%), but it rises to 10–20% in parts of Africa, the Middle and the Far East.

Vertical transmission from mother to child *in utero*, during parturition or soon after birth, is the usual means of transmission worldwide. This is related to the HBV replicative state of the mother (90% HBeAg+, 30% HBeAg–ve) and is uncommon in Africa where horizontal transmission (sib to sib) is common. HBV is not transmitted by breast-feeding.

Horizontal transmission occurs particularly in children through minor abrasions or close contact with other children, and HBV can survive on household articles, e.g. toys, toothbrushes, for prolonged periods.

HBV spread also occurs by the intravenous route (e.g. by transfusion of infected blood or blood products, or by contaminated needles used by drug users, tattooists or acupuncturists), or by close personal contact, such as during sexual intercourse, particularly in men having sex with men (25% of cases in the USA). The virus can be found in semen and saliva.

Hepatitis B virus (HBV)

The complete infective virion or Dane particle is a 42 nm particle comprising an inner core or nucleocapsid (27 nm) surrounded by an outer envelope of surface protein (HBsAg). This surface coat is produced in excess by the infected hepatocytes and can exist separately from the whole virion in serum and body fluid as 22 nm particles or tubules.

HBsAg contains a major 'a' antigenic determinant as well as several subtypes: 'd', 'y', 'w' and 'r'. Combinations of these subdeterminants (e.g. adr, adw, ayw and ayr) are used to classify HBV genotypes A–H, of which the main types are type A (35%), B (22%), C (31%) and D (10%). There is a strong correlation between genotypes and geographical areas. Genotype A in north-west Europe, North America and Central Africa; B in South-east Asia (including China, Taiwan and Japan); genotype C in South-east Asia; D in southern Europe, India and the Middle East; E in West Africa; F in South and Central America, in American Indians and in Polynesia; G in France and USA; and H in Central and South America. These genotypes have a bearing on, for example, the time to HBeAg seroconversion (B < C), response to interferon treatment (A > B; C > D) and the development of chronic liver disease (A < D).

The core or nucleocapsid is formed of core protein (HBcAg) containing incompletely double-stranded circular DNA and DNA polymerase/reverse transcriptase. One strand is almost a complete circle and contains overlapping genes that encode both structural proteins (pre-S, surface (S), core (C)) and replicative proteins (polymerase and X). The other strand

Figure 7.16 Hepatitis B virus (HBV) genome. The viral DNA is partially double-stranded (red incomplete circle and blue circle). The long strand (blue) encodes seven proteins from four overlapping reading frames (S, surface (Pre-S₁, Pre-S₂, S); c, core (Pre-C, C) P, polymerase (P) and X gene (X)). EcoRI restriction-enzyme-binding site is included as a reference point. DR, direct repeats.

is variable in length. DR1 and DR2 are direct repeats necessary for HBV synthesis during viral replication (Fig. 7.16).

HBeAg is a protein formed via specific self-cleavage of the pre-core/core gene product which is secreted separately by the cell.

Hepatitis B mutants

Mutations occur in the various reading frames of the HBV genome (Fig. 7.16). These mutants can emerge in patients with chronic HBV infection (escape mutants) or can be acquired by infection.

HBsAg mutants are produced by alterations in the 'a' determinants of the HbsAg proteins with usually a substitution of glycine for arginine at position 145. This results in changes in the antibody binding domain and the usual tests for HBsAg may be affected.

A mutation in the *pre-core region* when a guanosine (G) to adenosine (A) change creates a stop codon (TAG) prevents the production of HBeAg, but the synthesis of HBeAg is unaffected. To detect infectivity, HBV DNA must always be measured as no eAg will be present.

DNA polymerase mutants occur, particularly with directly-acting antiviral drugs.

Pathogenesis

Pre-S₁ and pre-S₂ regions are involved in attachment to an unknown receptor on the hepatocyte. After penetration into the cell, the virus loses its coat and the virus core is transported to the nucleus without processing. The transcription of HBV into mRNA takes place by the HBV DNA being converted into a closed circular form (Yc DNA), which acts as a template for RNA transcription.

Translation into HBV proteins (Table 7.6) as well as replication of the genome takes place in the endoplasmic reticulum; they are then packaged together and exported from the cell. There is an excess production of non-infective HbsAg particles which are extruded into the circulation.

The HBV is not directly cytopathic and liver damage is produced by the host cellular immune response.

Table 7.6 HBV proteins

HBV protein	Significance
Core	Protein of core particle; kinase activity (role in replication?)
Pre-core (HBeAg)	Pre-core/core cleaves to HBeAg; good marker of active replication and role in inducing immunotolerance
Surface (HBsAg)	Envelope protein of HBV; basis of current vaccine
Pre-S ₂ Pre-S ₁	HBV binding and entry into hepatocytes
Polymerase	
X protein	Transcriptional and transactivator activity

HBV-specific cytotoxic CD8 T cells recognize the viral antigen via HLA class I molecules on the infected hepatocytes. However, suppressor or regulatory T cells inhibit these cytotoxic cells, leading to viral persistence and chronic HBV infection. Th1 responses (interleukin-2, γ -interferon) are thought to be associated with viral clearance and Th2 (interleukins 4, 5, 6, 10, 13) responses with the development of chronic infection and disease severity. Viral persistence in patients with a very poor cell-mediated response leads to asymptomatic inactive chronic HBV infective state. However, a better response, results in continuing hepatocellular damage with the development of chronic hepatitis.

Chronic HBV infection progresses through a replicative and an integrated phase. In the *replicative phase* there is active viral replication with hepatic inflammation and the patient is highly infectious with HBeAg and HBV DNA positivity. At some stage the viral genome becomes *integrated* into the host DNA and the viral genes are then transcribed along with those of the host. At this stage, the level of HBV DNA in the serum is low and the patient is HBeAg negative and HBe antibody positive. The aminotransferases are now normal or only slightly elevated and liver histology shows little inflammation, often with cirrhosis. Hepatocellular carcinoma (HCC) develops in patients with this late-stage disease, but the mechanism is still unclear. The REVEAL Study (Risk Evaluation of Viral load Elevation and Associated Liver disease) showed that the risk of HCC was related to levels of HBV DNA rather than a raised aminotransferase (ALT). Integration of the viral DNA with the host-cell chromosomal DNA does appear to have a major role in carcinogenesis. There is evidence to implicate inactivation of p53-induced apoptosis by protein X (Table 7.6), allowing accumulation of abnormal cells and, eventually, carcinogenesis.

Clinical features of acute hepatitis

The sequence of events following acute HBV infection is shown in Figure 7.17. However, in many, the infection is subclinical. When HBV infection is acquired perinatally, an acute hepatitis usually does not occur as there is a high level of immunological tolerance and the virus persists in over 90%. If there is an acute clinical episode the virus is cleared in approximately 99% of patients as there is a good immune reaction. The clinical picture is the same as that found in HAV infection, although the illness may be more severe. In addition, a serum sickness-like immunological syndrome may be seen. This consists of rashes (e.g. urticaria or a maculopapular rash) and polyarthritis affecting small joints occurring in up to 25% of cases in the

Figure 7.17 Time course of the events and serological changes seen following infection with hepatitis B virus.

(a) Acute infection. *Antigens:* HBsAg appears in the blood from about 6 weeks to 3 months after an acute infection and then disappears. HBeAg rises early and usually declines rapidly. *Antibodies:* Anti-HBs appears late and indicates immunity. Anti-HBc is the first antibody to appear and high titres of IgM anti-HBc suggest an acute and continuing viral replication. It persists for many months. IgM anti-HBc may be the only serological indicator of recent HBV infection in a period when HBsAg has disappeared and anti-HBs is not detectable in the serum. Anti-HBe appears after the anti-HBc and its appearance relates to a decreased infectivity, i.e. a low risk.

(b) Development of chronic hepatitis followed by seroconversion. HBsAg persists and indicates a chronic infection (or carrier state). HBeAg persists and correlates with increased severity and infectivity and the development of chronic liver disease. When anti-HBe develops (seroconversion) the Ag disappears and there is a rise in ALT. HBV DNA suggests continual viral replication. For mutants, see text.

prodromal period. Fever is usual. Extrahepatic immune complex-mediated conditions such as an arteritis or glomerulonephritis are occasionally seen.

Investigations

These are generally the same as for hepatitis A.

Specific tests. The markers for HBV are shown in Table 7.7. HBsAg is looked for initially; if it is found, a full viral profile is then performed. In acute infection, as HBsAg may be cleared rapidly, anti-HBc IgM is diagnostic. HBV DNA is the most sensitive index of viral replication. HBV DNA has been shown to persist (using polymerase chain

Table 7.7 Significance of viral markers in hepatitis B

Antigens	
HBsAg	Acute or chronic infection
HBeAg	Acute hepatitis B
	Persistence implies:
	Continued infectious state
	development of chronicity
	Increased severity of disease
HBV DNA	Implies viral replication
	Found in serum and liver
	Levels indicate response to treatment
Antibodies	
Anti-HBs	Immunity to HBV; previous exposure; vaccination
Anti-HBe	Seroconversion
Anti-HBc	
IgM	Acute hepatitis B (high titre)
	Chronic hepatitis B (low titre)
IgG	Past exposure to hepatitis B (HBsAg-negative)

reaction (PCR) techniques) even when the e antibody has developed.

Course

The majority of patients recover completely, fulminant hepatitis occurring in up to 1%. Some patients go on to develop chronic hepatitis (p. 321), cirrhosis (p. 328) and hepatocellular carcinoma (p. 347) or have inactive chronic HBV infection. The outcome depends upon several factors, including the virulence of the virus and the immuno-competence and age of the patient. Some genetic factors, e.g. the presence of MHC class II genotype, may alter host defence to HBV.

Treatment for acute hepatitis

This is mainly symptomatic. However, patients should have their HBV markers monitored. Several experts suggest that entecavir or tenofovir should be given for the persistent presence of HBeAg beyond 12 weeks, and in some patients who are very ill.

Prevention and prophylaxis

Prevention depends on avoiding risk factors (see above). These include not sharing needles and having safe sex. Vertical transmission is discussed below. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood. These patients should be counselled about their infection. In developing countries, blood and blood products are still a hazard. Standard safety precautions in laboratories and hospitals must be enforced strictly to avoid accidental needle punctures and contact with infected body fluids.

Passive and active immunization

Vaccination is obligatory in most developed countries (but not the UK) as well as countries with high endemicity. Groups at high risk are: all healthcare personnel; members of emergency and rescue teams; morticians and embalmers; children in high-risk areas; people with haemophilia; patients in some psychiatric units; patients with chronic kidney disease/on dialysis units; long-term travellers; men who have sex with men (MSM), bisexual men and sex workers; intravenous drug users.

Combined prophylaxis (i.e. vaccination and immunoglobulin) should be given to: staff with accidental needle-stick injury; all newborn babies of HBsAg-positive mothers; regular

sexual partners of HBsAg-positive patients, who have been found to be HBV-negative.

For adults a dose of 500 IU of specific hepatitis B immunoglobulin (HBIG) (200 IU to newborns) is given and the vaccine (i.m.) is given at another site.

Active immunization

This is with a recombinant yeast vaccine produced by insertion of a plasmid containing the gene of HBsAg into a yeast.

Dosage regimen. Three injections (at 0, 1 and 6 months) are given into the deltoid muscle; this gives short-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with HIV infection or AIDS) have a poor antibody response; more frequent and larger doses are required. Antibody levels should be measured at 7–9 months after the initial dose in all at-risk groups. Antibody levels fall steadily after vaccination and booster doses may be required after approximately 3–5 years. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine.

Chronic HBV infection

Following an acute HBV infection, which may be subclinical, approximately 1–10% of patients will not clear the virus and will develop a chronic HBV infection. This occurs more readily with neonatal (90%) or childhood (20–50% below the age of 5 years) infection than when HBV is acquired in adult life (<10%).

Immune tolerant chronic HBV infection

Patients are asymptomatic and HBsAg and HBeAg positive with very high levels of serum HBV DNA, but normal liver function tests. Most have been infected perinatally so that this is common in Asians. They do not require treatment, but often in the third to fifth decade in life there is a change in host immunity with lymphocytes recognizing infected hepatocytes so that an acute hepatitis develops and chronic hepatitis can follow.

Inactive carrier with chronic HBV infection

There is a vast geographical variation in the incidence of inactive carriers of chronic hepatitis B. In the UK, patients are usually discovered incidentally by blood tests, such as when they are screened for donating blood for transfusion or when attending genital medicine or antenatal clinics. Patients have HBsAg in their serum and are HBeAg negative, HBe antibody positive, with levels of HBV DNA, which are below 400 iu/L in their serum. They have normal aminotransferase levels. Most remain HBsAg positive, but do not develop progressive liver disease, although rarely some patients have episodes of reactive hepatitis such as during chemotherapy for cancer or with bone marrow transplantation: antiviral prophylaxis is indicated. There is an annual spontaneous clearance rate of HBsAg of 1–2%.

Active chronic HBV infection

These patients have raised serum aminotransferases with evidence of HBV replication; they have HBe antigen and/or anti-HBe and HBV DNA in their serum. A liver biopsy shows chronic hepatitis.

Clinical features and investigations of active chronic hepatitis B

Chronic hepatitis is more frequent in men and it is often not preceded by an acute attack. The condition may be asymptomatic or may present as a mild, slowly progressive

hepatitis; 50% present with established chronic liver disease. Clinical relapses or 'flares' occur, sometimes associated with seroconversion (see below) of HBeAg to anti-HBe or vice versa.

Investigations show a moderate rise in aminotransferases and a slightly raised ALP. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, usually with HBe antigen, unless a mutant virus is involved (see p. 319).

Histologically, there is a full spectrum of changes from near normal with only a few lymphocytes and interface hepatitis to a full-blown cirrhosis. HBsAg may be seen as a 'ground-glass' appearance in the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or more specifically with immunohistochemical staining. HBcAg can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

Treatment for chronic hepatitis B

Indications for therapy are similar for HBeAg positive or negative patients with chronic hepatitis. Three criteria are used: serum HBV DNA levels, serum ALT levels and histological grade and stage:

- **Patients with moderate to severe active necroinflammation** and/or fibrosis in the liver biopsy with HBV DNA above 2000 iu/mL (approximately 10 000 copies/mL) and/or ALT above the upper limit of normal. Age and co-morbidities also affect the decision to treat and with which agents.
- **If cirrhosis is present**, treatment should be given independent of ALT or HBV DNA levels. Patients with decompensated cirrhosis can also be treated with oral antiviral agents, but liver transplantation may be required.
- **Immunotolerant patients**, usually young with persistently normal ALT and high HBV DNA levels, without evidence of liver disease, and without a family history of cirrhosis or hepatocellular cancer do not need therapy, but must receive follow-up.

The aim of treatment is the seroconversion of HBeAg when present to anti-HBe, and the reduction of HBV DNA to 400 iu/L or less measured by sensitive PCR techniques. In addition normalization of serum ALT, histological improvement in inflammation and fibrosis, and loss of HBsAg reflect a good response.

If HBeAg disappears, remission is usually sustained for many years. Patients usually remain HBsAg positive, but there is a small, but incremental loss of HBsAg/annum.

Antiviral agents

Interferon, entecavir and tenofovir are the most commonly used drugs (p. 93). Response to therapy is judged by a reduction in the HBV DNA level, and if HBeAg is present, by sero-conversion to anti-HBe.

Pegylated α -2a interferon (180 μ g once a week subcutaneously) gives response rates of 25–45% (depending on genotype – A and B respond best) after 48 weeks of treatment. Patients with higher serum aminotransferase values (3 \times the upper limit of normal), who are younger, with viral loads <10⁷ IU/mL respond best. Patients with concomitant HIV respond poorly and those with cirrhosis should not receive interferon.

Side-effects of treatment are many, with an acute flu-like illness occurring 6–8 h after the first injection. This usually disappears after subsequent injections, but malaise, headaches and myalgia are common; depression, reversible hair loss and bone marrow depression and infection may also

Table 7.8 Factors predictive of a sustained response to treatment in patients with chronic hepatitis B

Duration of disease	Short
Liver biochemistry	High serum aminotransferases
Histology	Active liver disease (mild to moderate)
Viral levels	Low HBV DNA levels
Other	Absence of immunosuppression Female gender Adult acquired Delta virus negative Rapidly of response to oral therapy

occur. The platelet count should be monitored. These drug reactions occur in up to 30% of patients, and the dose may have to be lowered.

Overall, the *response rate* (i.e. disappearance of HBeAg) is 25–40%. The success rate depends on factors shown in Table 7.8.

In older patients HBeAg usually disappears (sometimes due to changes in the viral genome). Many such patients have inactive disease but some reactivate without regaining HBeAg (HBeAg negative disease). They respond poorly to interferon but can be treated with nucleoside and nucleotide analogues. Patients who have developed viral mutations should be treated with a two-drug combination.

Oral therapy

- **Entecavir** is very effective and reduces HBV DNA quickly, and there is little viral resistance. Serum HBV DNA becomes negative in 67% (HBeAg-positive patients) and 90% (HBeAg-negative patients) by 48 weeks. It should not be used in patients with lamivudine-induced mutants, but can be used if adefovir mutations have occurred.
- **Tenofovir** is also very effective, has a similar potency to entecavir, and as yet no resistance mutants have been described. It is used for HIV patients with HBV infection. It can also be used in patients with lamivudine mutations, but not on its own for adefovir mutations.
- **Lamivudine**, 100 mg/day given orally, is well tolerated. However, by 4 years, 80% develop viral resistance due to YMDD mutant (tyrosine (Y), methionine (M), aspartate (D)), which itself causes hepatitis. Lamivudine monotherapy is no longer recommended.

The duration of all treatment is probably lifelong and is still being assessed.

Prognosis

The clinical course of hepatitis B is very variable and treatments have improved survival, and stopped progression of fibrosis and enabled regression of fibrosis to occur. Progression from the acute to the chronic phase depends on the age at which infection is acquired. Established cirrhosis is associated with a poor prognosis. Hepatocellular carcinoma is a frequent association and is one of the most common carcinomas in HBV-endemic areas such as the Far East. Surveillance for HCC must continue even when HBV DNA is negative in patients who have HBsAg and are not treated, and also in these rendered negative by therapy. The incidence of HCC is being reduced by routine HBV vaccination of all children.

Hepatitis D

This is caused by the hepatitis D virus (HDV or delta virus) which is an incomplete RNA particle enclosed in a shell of HbsAg and belongs to the Deltaviridae family. It is unable to replicate on its own but is activated by the presence of HBV. It is particularly seen in intravenous drug users but can affect all risk groups for HBV infection. Hepatitis D viral infection can occur either as a:

- **Co-infection** of HDV and HBV which is clinically indistinguishable from an acute icteric HBV infection, but a biphasic rise of serum aminotransferases may be seen. *Diagnosis* is confirmed by finding serum IgM anti-HDV in the presence of IgM anti-HBc. IgM anti-delta appears at 1 week and disappears by 5–6 weeks (occasionally 12 weeks) when serum IgG antidelta is seen. The HDV RNA is an early marker of infection. The infection may be transient but the clinical course is variable.
- **Superinfection** which results in an acute flare-up of previously quiescent chronic HBV infection. A rise in serum AST or ALT may be the only indication of infection. *Diagnosis* is by finding HDV RNA or serum IgM anti-HDV at the same time as IgG anti-HBc. Active HBV DNA synthesis is reduced by delta superinfection and patients are usually negative for HBeAg with low HBV DNA.

Fulminant hepatitis can follow both types of infection but is more common after co-infection. HDV RNA in the serum and liver can be measured and is found in acute and chronic HDV infection.

Chronic D hepatitis

This is a relatively infrequent chronic hepatitis, but spontaneous resolution is rare. Between 60% and 70% of patients will develop cirrhosis, and more rapidly than with HBV infection alone. In 15% the disease is rapidly progressive with development of cirrhosis in only a few years. The diagnosis is made by finding anti-delta antibody in a patient with chronic liver disease who is HBsAg positive. It can be confirmed by finding HDV in the liver or HDV RNA in the serum by reverse transcription PCR. *Treatment* for patients with active liver disease (raised ALT levels and/or inflammation on biopsy) is with pegylated α -2a interferon and adefovir for 12 months, with a response rate of about 30%.

Hepatitis C**Epidemiology**

The prevalence rate of infection in healthy blood donors is about 0.02% in Northern Europe, 1–3% in Southern Europe (possibly linked to intramuscular injections of vaccines or other medicines), 6% in Africa, and in Egypt the rates are as high as 19% owing to parenteral antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products and was common in people with haemophilia treated before screening of blood products was introduced. The incidence in intravenous drug users is high (50–60%). The low rate of hepatitis C (HCV) infection in high-risk groups – such as men who have sex with men, sex workers and attendees at STI clinics – suggests a limited role for sexual transmission. Vertical transmission from a healthy mother to child can occur, but is very rare. Other routes of community-acquired infection (e.g. close contact) are extremely rare. In 20% of cases the exact mode of transmission is unknown.

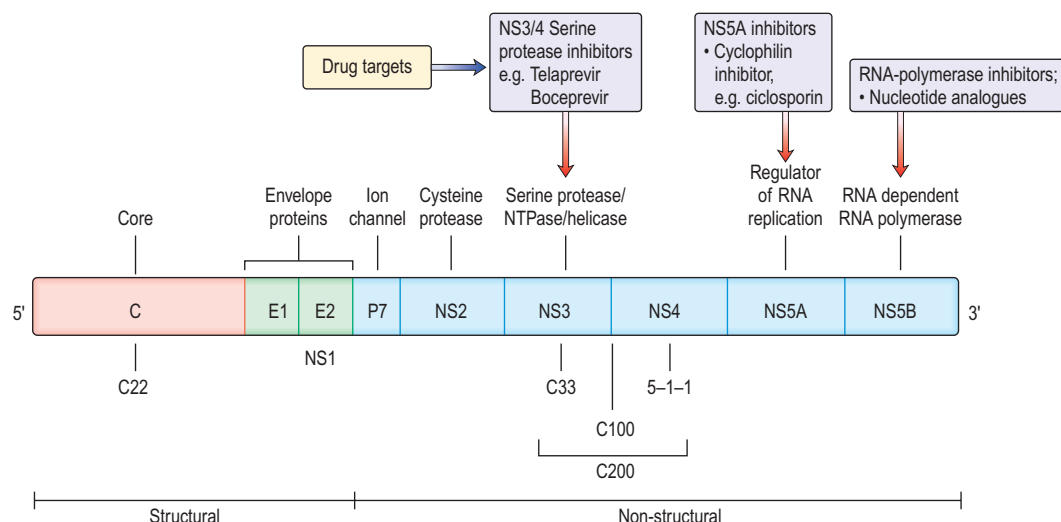

Figure 7.18 Hepatitis C virus. Diagram showing a single-stranded RNA virus with viral proteins. Targets for recent drugs are shown. C, core; NS, non-structural; E, envelope. Telaprevir and boceprevir are NS 3/4 protease inhibitors.

An estimated 240 million people are infected with this virus worldwide.

Hepatitis C virus (HCV)

HCV is a single-stranded RNA virus of the Flaviviridae family. The RNA genome is approximately 10 kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (Fig. 7.18). Comparisons of subgenomic regions, such as E1, NS4 or NS5, have allowed variants to be classified into six genotypes. Variability is distributed throughout the genome with the non-structural gene of different genotypes showing 30–50% nucleotide sequence disparity. Genotypes 1a and 1b account for 70% of cases in the USA and 50% in Europe. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISA). The current assay, ELISA-3, incorporates antigens NS3, NS4 and NS5 regions.

Clinical features

Most acute infections are asymptomatic, with about 10% of patients having a mild flu-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transaminase values at health checks or with chronic liver disease. Extrahepatic manifestations are seen, including arthritis, cryoglobulinaemia with or without glomerulonephritis and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome and non-Hodgkin's lymphoma.

Diagnosis

This is frequently by exclusion in a high-risk individual with negative markers for HAV, HBV and other viruses. A drug cause for hepatitis should be excluded if possible. HCV RNA can be detected from 1 to 8 weeks after infection. Anti-HCV tests are usually positive 8 weeks from infection.

Treatment

Interferon has been used in acute cases to prevent chronic disease. Needle-stick injuries must be followed and treated early if there is evidence of HCV viraemia, usually re-tested for, at 4 weeks.

Course

Some 85–90% of asymptomatic patients develop chronic liver disease. A higher percentage of symptomatic patients 'clear' the virus with only 48–75% going on to chronic liver disease (p. 312). Cirrhosis develops in about 20–30% within 10–30 years and of these patients between 7% and 15% will develop hepatocellular carcinoma. The course is adversely affected by co-infection with HBV and/or HIV, and by alcohol consumption, which should be discouraged.

Chronic hepatitis C infection

Pathogenesis

As with hepatitis B infection, cytokines in the Th2 phenotypes are profibrotic and lead to the development of chronic infection. A dominant CD4 Th2 response with a weak CD8 γ -interferon response may lead to rapid fibrosis. Th1 cytokines are antifibrotic and thus a dominant CD4 Th1 and CD8 cytolytic response may cause less fibrosis. Viral load and viral genotype do not affect rate of fibrosis; persistence of HCV infection has been shown to be associated with HLA-DRB1*0701 and DRB4*0101. Other factors also have an effect on the development of fibrosis, particularly male gender, high alcohol intake, a fatty liver and diabetes.

Clinical features

Patients with chronic hepatitis C infection are usually asymptomatic, the disease being discovered only following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating (Fig. 7.19) and some patients have a persistently normal ALT (25%), the disease being detected by checking HCV antibodies (e.g. in blood donors).

Severe chronic hepatitis (25%) and even cirrhosis can be present with only minimal elevation in aminotransferases, but progression is very uncommon in those with a persistently normal ALT. Fatigue is the commonest symptom with sometimes nausea, anorexia and weight loss, which do not correlate with disease activity.

Diagnosis

This is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. HCV RNA should be assayed

Figure 7.19 Time course of the events and serological changes seen following infection with hepatitis C virus.

using quantitative HCV-RNA PCR. The viraemia is usually variable; less than 600 000 iu/mL signifies a greater likelihood of response to antiviral therapy.

The HCV genotype should be characterized in patients who are to be given treatment (see below).

Liver biopsy is indicated if treatment is being considered, especially for genotypes 1 and 4. Non-invasive methods for the diagnosis of fibrosis such as serum markers and elastography (p. 309) can replace the need for biopsy in many cases and are useful in follow-up. The changes on liver biopsy are highly variable. Sometimes only minimal inflammation is detected, but in most cases the features of chronic hepatitis are present, as described (p. 316). Lymphoid follicles are often present in the portal tracts, and fatty change is frequently seen. Histological scoring systems such as METAVIR and Ishak evaluate the inflammation and fibrosis and are used to guide therapy.

Treatment

Treatment (Fig. 7.20) is appropriate for patients with chronic hepatitis on liver histology and/or who have HCV RNA in their serum whether or not serum aminotransferases are raised. The presence of cirrhosis is not a contraindication, but therapeutic responses are less likely. Patients with decompensated cirrhosis should be considered for transplantation. The aim of treatment is to eliminate the HCV RNA from the serum in order to:

- stop the progression of active liver disease
- prevent the development of hepatocellular carcinoma.

A clinical cure is determined by a sustained virological response (SVR), which is defined by a negative HCV-RNA by PCR, 6 months after the end of therapy.

Antiviral agents

Current treatment is combination therapy with pegylated interferon (Peg), which is interferon with a polyethylene-glycol tail (α -2a 180 μ g/week or α -2b 1.5 μ g/kg/week), and ribavirin (R) (1000–1200 mg/day for genotype 1 and 4, 800 mg/day for genotype 2 or 3). For genotype 1 only, Peg/R is combined with either of two NS3 protease inhibitors, telaprevir and boceprevir. The combination increases SVR rates compared with Peg/R, to 70–75% or more, in treatment naive patients, or previous relapsers to Peg/R, 55–60% in previous partial responders, and to 30% in previous null responders. Other drugs, NS5B protease inhibitors, cyclophilin inhibitors, new types of interferon and

ribavirin analogues are all being developed which will change future treatment algorithms. Treatment duration with Peg/R alone is 12 months for genotypes 4 and 6, and 6 months for genotypes 2 or 3, and as short as 6 months for some genotype 1 patients receiving triple therapy.

Pawlotsky J-M. The Results of Phase III Clinical Trials with Telaprevir and Boceprevir, presented at the Liver Meeting 2010: a new standard of care for Hepatitis C Virus Genotype 1, but with issues still pending. *Gastroenterology* 2011; 140: 746–760.

Factors affecting response are an HCV RNA viral load of >600 000 IU/L, abnormal body mass index (BMI), older age, male gender, insulin resistance, non-genotype 2 or 3, and CC homozygosity for the IL-28 polymorphism in genotype 1 patients (confers a 70% chance of SVR with Peg/R, compared with TT homozygosity for which SVR is about 20%), which is related to an interferon response gene.

This polymorphism is more common in ethnic Asians than in Caucasians, and is less common in African American and Afro-Caribbeans, and has less influence in genotype-2 or -3 patients or triple therapy with protease inhibitors.

Side-effects of interferon are described on page 321. Ribavirin is usually well tolerated but side-effects include a dose-related haemolysis, pruritus and nasal congestion. Telaprevir causes a rash and anaemia, and boceprevir causes dysgeusia and anaemia. Pregnancy must be avoided with antiviral therapy.

Monitoring results. A rapid virological response is a negative HCV-RNA by PCR at 4 weeks (RVR), which is a very good surrogate of SVR. In about 80% of patients tolerating full dosage of Peg/R, an early virological response (EVR) occurs which is defined as becoming HCV RNA negative or having at least a 2 log reduction in the first 12 weeks. If this is not achieved, the patient is a null responder, and so unlikely to respond that Peg/R should be stopped. If the HCV RNA is positive at 24 weeks, having been below the threshold at 12 weeks, Peg/R should be stopped; if negative, treatment should continue for 72 weeks (genotype 4). For genotype 2 and 3, an absent RVR and/or a positive HCV RNA (but more than a 2 log drop) at 12 weeks leads to 48 weeks of therapy. If HCV RNA is undetectable at 4 weeks, treatment for patients with genotype 2 can be stopped at 12–16 weeks and for genotype 1 (if <600 000 iu/mL at baseline) at 6 months.

A sustained response is clearance of HCV RNA at 6 months after the end of therapy. It is a good surrogate marker for the resolution of the hepatitis. This is achieved in 70–75% of genotype 1 patients with triple therapy, and with Peg/R alone in 50% of patients with genotype 4, and 80% in genotype 2 or 3. In sustained responders relapse is unlikely and histological progression is halted. Best results are obtained in young patients with low HCV RNA levels and genotype 2 or 3.

Oral daclatasvir, a highly selective HCV NS5A replication complex inhibitor, with oral asunaprevir, a highly active HCV NS3 protease inhibitor, have shown good sustained responses in patients with HCV genotype 1 who have been resistant to other therapy. An oral two drug therapy with SVRs approaching are likely in the future.

Hepatitis E

Hepatitis E virus (HEV) is an RNA virus (herpesvirus) (Fig. 7.21) causing a hepatitis clinically very similar to hepatitis A. It is enterally transmitted, usually by contaminated water, with 30% of dogs, pigs and rodents carrying the virus. Epidemics have been seen in many developing countries and sporadically in developed countries, in patients who have had contacts with farm animals or travel abroad. It has a mortality from fulminant hepatic failure of 1–2%, which rises to 20% in pregnant women. There is no carrier state and it does not progress to chronic liver disease except in some immunosuppressed patients. An ELISA for IgG and IgM anti-HEV is available for diagnosis. HEV RNA can be detected in the serum or stools by PCR. Prevention and control depend on good sanitation and hygiene; a vaccine has been developed and used successfully in China.

Figure 7.21 Hepatitis E genome – showing a single-stranded RNA genome with three open reading frames (ORF).

Hepatitis non-A–E

Approximately 10–15% of acute viral hepatitis cannot be typed and are described as hepatitis non-A–E. GB agent (HGV hepatitis G virus) and TTV (transfusion-transmitted virus) agents have not been documented as causing disease in humans.

ACUTE HEPATITIS DUE TO OTHER INFECTIOUS AGENTS

Abnormal liver biochemistry is frequently found in a number of acute infections. The abnormalities are usually mild and have no clinical significance.

Infectious mononucleosis (see also p. 99). This is due to the Epstein–Barr (EB) virus. Mild jaundice associated with minor abnormalities of liver biochemistry is extremely common, but ‘clinical’ hepatitis is rare. Hepatic histological changes occur within 5 days of onset; the sinusoids and portal tracts are infiltrated with large mononuclear cells but the liver architecture is preserved. A Paul–Bunnell or Monospot test is usually positive, and atypical lymphocytes are present in the peripheral blood. Treatment is symptomatic.

Cytomegalovirus (CMV) (see also p. 99). This can cause acute hepatitis, usually a glandular fever type syndrome in healthy individuals, but is more severe in those with an impaired immune response. Only the latter need treatment with valganciclovir or ganciclovir.

CMV DNA is positive in blood; CMV IgM is also positive, but there are false-positive reactions.

The liver biopsy shows intranuclear inclusions and giant cells.

Herpes simplex (see also p. 97). Very occasionally the herpes simplex virus causes a generalized acute infection, particularly in the immunosuppressed patient, and occasionally in pregnancy. Aminotransferases are usually massively elevated. Liver biopsy shows extensive necrosis. Aciclovir is used for treatment.

Toxoplasmosis (see also p. 149). The clinical picture is similar to infectious mononucleosis, with abnormal liver biochemistry, but the Paul–Bunnell test is negative.

Yellow fever (see also p. 329). This viral infection is carried by the mosquito *Aedes aegypti* and can cause acute hepatic necrosis. There is no specific treatment.

Acute hepatitis due to other infectious agents

FULMINANT HEPATIC FAILURE (FHF)

This is defined as severe hepatic failure in which encephalopathy develops in under 2 weeks in a patient with a previously normal liver (occasionally in some patients with previous liver damage; e.g. D virus superinfection in a previous carrier of HBsAg, Budd–Chiari syndrome or Wilson's disease). Cases that evolve at a slower pace (2–12 weeks) are called subacute or subfulminant hepatic failure. FHF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (Table 7.9). The causes vary throughout the world; most cases are due to viral hepatitis, but paracetamol overdose is common in the UK (50% of cases). HCV does not usually cause FHF although exceptional cases have been reported from Japan and India.

Histologically, there is multiacinar necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (p. 346), Reye's syndrome (p. 348) or following tetracycline administration intravenously.

Clinical features

Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies from slight drowsiness, confusion and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Feto hepaticus is common, but ascites and splenomegaly are rare. Fever, vomiting, hypotension and hypoglycaemia occur. Neurological examination shows spasticity and hyperreflexia; plantar responses remain flexor until late. Cerebral oedema develops in 80% of patients with FHF but is far less common with subacute failure and its consequences of intracranial hypertension and brain herniation account for about 25% of the causes of death. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, kidney failure (hepatorenal syndrome and acute tubular necrosis) and pancreatitis.

Investigations

There is hyperbilirubinaemia, high serum aminotransferases and low levels of coagulation factors, including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease as they tend to fall along with the albumin with progressive liver damage. An EEG is sometimes

Box 7.1 Transfer criteria to specialized units for patients with acute liver injury

- INR >3.0
- Presence of hepatic encephalopathy
- Hypotension after resuscitation with fluid
- Metabolic acidosis
- Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

helpful in grading the encephalopathy. Ultrasound will define liver size and may indicate underlying liver pathology.

Treatment

There is no specific treatment, but patients should be managed in a specialized unit. Transfer criteria to such units are shown in Box 7.1. Supportive therapy as for hepatic encephalopathy is necessary (see p. 337). When signs of raised intracranial pressure (which is sometimes measured directly) are present, 20% mannitol (1 g/kg bodyweight) should be infused intravenously; this dose may need to be repeated. Dexamethasone is of no value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia should be anticipated and corrected with 10% dextrose infusion (checked by 2-hourly dipstick testing), potassium, calcium, phosphate and magnesium supplements. Hyponatraemia should be corrected with hypertonic saline. Coagulopathy is managed with intravenous vitamin K, platelets, blood or fresh frozen plasma. Haemorrhage may be a problem and patients are given a proton pump inhibitor (PPI) to prevent gastrointestinal bleeding. Prophylaxis against bacterial and fungal infection is routine, as infection is a frequent cause of death and may preclude liver transplantation. Suspected infection should be treated immediately with suitable antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with FHF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see below).

Course and prognosis

In mild cases (grades I and II encephalopathy with drowsiness and confusion), two-thirds of the patients will survive. The outcome of severe cases (grades III and IV encephalopathy with stupor or deep coma) is related to the aetiology. In special units, 70% of patients with paracetamol overdosage and grade IV coma survive, as do 30–40% patients with HAV or HBV hepatitis. Poor prognostic variables indicating a need to transplant the liver are shown in Box 7.2.

AUTOIMMUNE HEPATITIS

This condition occurs most frequently in women. In type I (see below) there is an association with other autoimmune diseases (e.g. pernicious anaemia, thyroiditis, coeliac disease and Coombs'-positive haemolytic anaemia) and 60% of cases are associated with HLA-DR3, DR52a loci, HLA-DRB1*0301 and HLA-DRB2*0401. In Asians, the condition is associated with HLA-DR4.

Pathogenesis

The cause is unknown. It is proposed, in a genetically pre-disposed person, that an environmental agent (perhaps a

virus) causes a sequence of T cell mediated events against liver antigens, producing a progressive necroinflammatory process which results in fibrosis and cirrhosis. *In vitro* observations have shown that there is a defect of suppressor (regulatory) T cells which may be primary or secondary. However, no clear mechanism causing the inflammation has been found.

Clinical features

There are two peaks in presentation. In the peri- and post-menopausal group, patients may be asymptomatic or present with fatigue, the disease being discovered by abnormalities in liver biochemistry or because of signs of chronic liver disease on routine examination. In the teens and early 20s, the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis with hepatosplenomegaly, cutaneous striae, acne, hirsutes, bruises and, sometimes, ascites. An ill patient can also have features of an autoimmune disease with a fever, migratory polyarthritis, glomerulonephritis, pleurisy, pulmonary infiltration or lung fibrosis.

There are rare overlap syndromes with primary biliary cirrhosis and primary sclerosing cholangitis, existing concomitantly or developing consecutively.

Investigations

Liver biochemistry

The serum aminotransferases are high, with lesser elevations in the ALP and bilirubin. The serum γ -globulins are high, frequently twice normal, particularly the IgG. The biochemical pattern is similar in both types.

Haematology

A mild normochromic normocytic anaemia with thrombocytopenia and leucopenia is present, even before portal hypertension and splenomegaly. The prothrombin time is often high.

Autoantibodies

Two types of autoimmune hepatitis have been recognized:

- **Type I with antibodies** (titres >1:80)
 - anti-nuclear (ANA)
 - anti-smooth muscle (anti-actin)
 - soluble liver antigen (anti SLA/LP): 10–30% of cases.

This occurs most frequently in girls and young women.

- **Type II with antibodies:** anti-liver/kidney microsomal (anti-LKM1). The main target is cytochrome P4502D6 (CYP2D6) on liver cell plasma membranes.

Approximately 13% of patients lack the above autoantibodies.

Liver biopsy

This shows the changes of chronic hepatitis described previously. The amount of interface hepatitis is variable, but tends to be high in untreated patients. Lymphoid follicles are less often seen than in hepatitis C, and plasma cell infiltration is frequent. Approximately one-third of patients have cirrhosis at presentation.

Treatment

Budesonide 3 mg \times 2 or 3 daily has fewer side-effects than prednisolone and is now the preferred treatment. Alternatively, prednisolone 30 mg is given daily for at least 2 weeks, followed by a slow reduction and then a maintenance dose of 10–15 mg daily. Azathioprine should be added, 1–2 mg/kg daily, as a steroid-sparing agent and in some patients as sole long-term maintenance therapy. Levels of thiopurine methyltransferase should be obtained. Mycophenolate, ciclosporin and tacrolimus have been used in resistant cases.

Course and prognosis

Steroid and azathioprine therapy induce remission in over 80% of cases. This response forms part of the diagnostic criteria for autoimmune hepatitis. Treatment is lifelong in most cases. Those with initial cirrhosis are more likely to relapse following treatment withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur. Hepatocellular carcinoma occurs less frequently than with viral-induced cirrhosis.

DRUG-INDUCED CHRONIC HEPATITIS

Several drugs can cause a chronic hepatitis which clinically bears many similarities to autoimmune hepatitis. Patients are often female, present with jaundice and hepatomegaly, have raised serum aminotransferases and globulin levels, and LE cells and anti-LKM1 antibodies may be detected. Improvement follows drug withdrawal but exacerbations can occur with drug reintroduction. Isoniazid, amiodarone and methotrexate can lead to chronic histological changes. With rare exceptions patients with pre-existing chronic liver disease are not more susceptible to drug injury.

Chronic alcoholic liver disease can occasionally have histological appearances more like a chronic hepatitis.

CHRONIC HEPATITIS OF UNKNOWN CAUSE

As more and more people are having routine blood tests, mild elevations in the serum aminotransferases and γ -GT are found. Many of these patients have no symptoms and no evidence of liver disease clinically. All known aetiological agents should be excluded (see above), and tests carried out to exclude primary biliary cirrhosis, primary sclerosing

Fulminant hepatic failure (FHF)

Autoimmune hepatitis

Drug-induced chronic hepatitis

Chronic hepatitis of unknown cause

Chronic active hepatitis showing moderate inflammation with interface hepatitis ($\times 10$).

cholangitis, Wilson's disease, haemochromatosis and α_1 -antitrypsin deficiency. Risk factors for NAFLD should be evaluated.

Liver biopsy should be performed if the elevation in the aminotransferases continues for over a year, to confirm the presence of chronic hepatitis, but often nonspecific changes are found.

NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD)

This is an increasingly recognized condition that can lead to cirrhosis (in 1%) and hepatocellular carcinoma. NAFLD is estimated to affect 3–6% of the population in the USA and of these, 1–3% have non-alcoholic steatohepatitis (NASH).

Histological changes are a spectrum similar to those of alcohol-induced hepatic injury, and range from simple fatty change to fat and inflammation (steatohepatitis, NASH), with or without fibrosis, to cirrhosis.

Oxidative stress injury and other factors lead to lipid peroxidation in the presence of fatty infiltration and inflammation results. Fibrosis then may occur which is enhanced by insulin resistance, which induces connective tissue growth factor. **Risk factors** for NAFLD are obesity, hypertension, type 2 diabetes and hyperlipidaemia, such that NAFLD is considered the liver component of the metabolic syndrome. Insulin resistance is universal.

Most patients are asymptomatic; hepatomegaly may be present. Obesity is frequent, but may be absent. Mild increases in serum aminotransferases and/or γ -GT (with ALT > AST) are frequently the sole abnormality in the liver biochemistry.

Diagnosis is by demonstration of a fatty liver, usually on ultrasound, with the exclusion of other causes of liver injury, e.g. alcohol. *Liver biopsy* allows staging of the disease but when this should be performed is unclear as there are no definitive guidelines. Most would biopsy if the ALT is persistently over twice normal.

Elastography (p. 309) is being used to evaluate the degree of fibrosis.

Management. Currently weight loss, exercise, strict control of hypertension, diabetes and lipid levels are the only treatments. The risk of death related to cardiovascular risk factors is greater than that due to liver disease. Fatty liver on its own does not progress. Once there is associated inflammation there is a risk of progression. Factors indicating progression are unknown, but diabetic patients are most at risk. Thiazolidinediones (p. 1011), which ameliorate insulin resistance, are being evaluated – histological improvement has been documented in short-term studies. Liver transplantation is reserved for end-stage cirrhosis, but the condition may recur. Regular follow-up is indicated, particularly for patients with NASH.

CIRRHOSIS

Cirrhosis results from the necrosis of liver cells followed by fibrosis and nodule formation. The liver architecture is diffusely abnormal and this interferes with liver blood flow and function. This derangement produces the clinical features of portal hypertension and impaired liver cell function.

Aetiology

The causes of cirrhosis are shown in Table 7.10. Alcohol is now the most common cause in the West, but viral infection

Table 7.10 Causes of cirrhosis

Common	Others
Alcohol	Biliary cirrhosis:
Hepatitis B \pm D	Primary
Hepatitis C	Secondary
Non-alcoholic fatty liver disease	Autoimmune hepatitis
	Hereditary haemochromatosis
	Hepatic venous congestion
	Budd–Chiari syndrome
	Wilson's disease
	Drugs (e.g. methotrexate)
	α_1 -Antitrypsin deficiency
	Cystic fibrosis
	Galactosaemia
	Glycogen storage disease
	Veno-occlusive disease
	Idiopathic (cryptogenic)
	? Other viruses

Figure 7.22 Pathogenesis of fibrosis. The normal liver is shown on the left. Activation of the stellate cell is followed by proliferation of fibroblasts and the deposition of collagen.

is the most common cause worldwide. With the identification of HCV, and recognition of non-alcoholic fatty liver disease (NAFLD), idiopathic (cryptogenic) cirrhosis is diagnosed infrequently. Young patients with cirrhosis must be investigated to exclude treatable causes (e.g. Wilson's disease).

Pathogenesis

Chronic injury to the liver results in inflammation, necrosis and, eventually, fibrosis (Fig. 7.22). Fibrosis is initiated by activation of the stellate cells (see p. 304). Kupffer cells, damaged hepatocytes and activated platelets are probably involved. Stellate cells are activated by many cytokines and their receptors, reactive oxygen intermediates and other paracrine and autocrine signals.

In the early stage of activation the stellate cells become swollen and lose retinoids with upregulation of receptors for proliferative and fibrogenic cytokines, such as platelet-derived growth factor (PDGF), and transforming growth factor β_1 (TGF- β_1). TGF- β_1 is the most potent fibrogenic mediator identified so far. Inflammatory cells contribute to fibrosis via cytokine secretion.

In the space of Disse, the normal matrix is replaced by collagens, predominantly types 1 and 3, and fibronectin. Subendothelial fibrosis leads to loss of the endothelial fenestrations (openings) and this impairs liver function. Collagenases (matrix metalloproteinases, MMPs) are able to degrade this collagen but are inhibited by tissue inhibitors of metalloproteinases (TIMPs), which are increased in human

liver fibrosis. There is accumulating evidence that liver fibrosis is reversible, particularly when inflammation is reduced on a long-term basis, e.g. by suppressing or eliminating viruses.

Pathology

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa and loss of the normal lobular architecture within the nodules (Fig. 7.23a). Two types of cirrhosis have been described which give clues to the underlying cause:

- **Micronodular cirrhosis.** Regenerating nodules are usually <3 mm in size and the liver is involved uniformly. This type is often caused by ongoing alcohol damage or biliary tract disease.
- **Macronodular cirrhosis.** The nodules are of variable size and normal acini may be seen within the larger nodules. This type is often seen following chronic viral hepatitis.

A mixed picture with small and large nodules is sometimes seen.

Symptoms and signs are described on page 312.

Investigations

These are performed to assess the severity and type of liver disease.

Severity

- **Liver function.** Serum albumin and prothrombin time are the best indicators of liver function: the outlook is poor with an albumin level below 28 g/L. The prothrombin time is prolonged commensurate with the severity of the liver disease (Box 7.3).

Box 7.3 Scoring systems in cirrhosis

(a) Modified Child–Pugh classification

Score	1	2	3
Ascites	None	Mild	Moderate/severe
Encephalopathy	None	Mild	Marked
Bilirubin (μmol/L)	<34	34–50	>50
Albumin (g/L)	>35	28–35	<28
Prothrombin time (seconds over normal)	<4	4–6	>6

Add above scores for your patient for survival figures below

Grade (scores)	% survival		
	1 year	5 years	10 years
Child's A (<7)	82	45	25
Child's B (7–9)	62	20	7
Child's C (10+)	42	20	0

(b) Model of end-stage liver disease (MELD)

$3.8 \times \text{LN (bilirubin in mg/dL)} + 9.6 \times \text{LN (creatinine in mg/dL)} + 11.2 \times \text{LN (INR)} + 6.4$

To convert:

- bilirubin from μmol/L to mg/dL divide by 17
- creatinine from μmol/L to mg/dL divide by 88.4

LN, natural logarithm; INR, international normalized ratio. MELD scores (with no complications): 1-year survival 97% (score <10); 70% (score 30–40).

- **Liver biochemistry.** This can be normal, depending on the severity of cirrhosis. In most cases there is at least a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis all biochemistry is deranged.
- **Serum electrolytes.** A low sodium indicates severe liver disease due to a defect in free water clearance or to excess diuretic therapy.
- **Serum creatinine.** An elevated concentration >130 μmol/L is a marker of worse prognosis.

In addition, serum α-fetoprotein if >200 ng/mL is strongly suggestive of the presence of a hepatocellular carcinoma.

Type

This can be determined by:

- Viral markers
- Serum autoantibodies
- Serum immunoglobulins
- Iron indices and ferritin
- Copper, caeruloplasmin (p. 341)
- α₁-Antitrypsin (p. 341).

Serum copper and serum α₁-antitrypsin should always be measured in young cirrhotics. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (p. 339).

Imaging

- **Ultrasound examination.** This can demonstrate changes in size and shape of the liver. Fatty change and fibrosis produce a diffuse increased echogenicity. In established cirrhosis there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. It is useful in detecting hepatocellular carcinoma. *Elastography* is being used in diagnosis and follow-up to avoid liver biopsy (p. 309).
- **CT scan** (see p. 310). Figure 7.23c,d shows hepatosplenomegaly, and dilated collaterals are seen in chronic liver disease. Arterial phase-contrast-enhanced scans are useful in the detection of hepatocellular carcinoma.
- **Endoscopy** is performed for the detection and treatment of varices, and portal hypertensive gastropathy. Colonoscopy is occasionally performed for colopathy.
- **MRI scan.** This is useful in the diagnosis of both malignant and benign tumours such as haemangiomas. MR angiography can demonstrate the vascular anatomy and MR cholangiography the biliary tree.

Liver biopsy

This is usually necessary to confirm the type and severity of liver disease. The core of liver often fragments and sampling errors may occur in macronodular cirrhosis. Special stains are required for iron and copper, and various immunocytochemical stains can identify viruses, bile ducts, angiogenic structures and oncogenic markers. Chemical measurement of iron and copper is necessary to confirm diagnosis of iron overload or Wilson's disease. Adequate samples in terms of length and number of complete portal tracts are necessary for diagnosis and for staging/grading of chronic viral hepatitis. Digital image analysis of picroSirius red staining can be used to quantitate collagen in biopsy specimens (Fig. 7.23b).

Non-alcoholic fatty liver disease (NAFLD)

Cirrhosis

Cirrhosis (×10).

Figure 7.23 Pathology of cirrhosis.

(a) Histological appearance showing nodules of liver tissue of varying size surrounded by fibrosis.

(b) PicroSirius red stain of collagen used for morphometric evaluation of fibrosis.

(c) CT scan showing an irregular lobulated liver. There is splenomegaly and enlargement of collateral vessels beneath the anterior abdominal wall (arrows) as a result of portal hypertension.

(d) CT image showing cirrhosis, with a patent portal vein and no space-occupying lesion.

Management

Management is that of the complications seen in decompensated cirrhosis. Patients should have 6-monthly ultrasound to detect the early development of a hepatocellular carcinoma (see p. 347), as all therapeutic strategies work best with small single tumours.

Treatment of the underlying cause may arrest or occasionally reverse the cirrhotic changes (see below). Patients with compensated cirrhosis should lead a normal life. The only dietary restriction is to reduce salt intake. Aspirin and NSAIDs should be avoided. Alcohol should be avoided, although if the cirrhosis is not due to alcohol and not due to viral hepatitis, small amounts not taken on a regular basis are probably not harmful.

Course and prognosis

This is extremely variable, depending on many factors, including the aetiology and the presence of complications. Poor prognostic indicators are given in Table 7.11. Development of any complication usually worsens the prognosis. In

Table 7.11 Poor prognostic indicators in cirrhosis

Blood tests

- Low albumin (<28 g/L)
- Low serum sodium (<125 mmol/L)
- Prolonged prothrombin time >6 s above normal value
- Raised creatinine >130 μ mol/L

Clinical

- Persistent jaundice
- Failure of response to therapy
- Ascites
- Haemorrhage from varices, particularly with poor liver function
- Neuropsychiatric complications developing with progressive liver failure
- Small liver
- Persistent hypotension
- Aetiology (e.g. alcoholic cirrhosis, if the patient continues drinking)

general, the 5-year survival rate is approximately 50%, but this also varies depending on the aetiology and the stage at which the diagnosis is made.

There are a number of prognostic classifications based on modifications of Child's grading (A, B and C; see [Box 7.3](#)) and the model for end-stage disease (MELD), based on serum bilirubin, creatinine and INR, which is widely used as a predictor of mortality in patients awaiting liver transplantation.

Liver transplantation

This is an established treatment for a number of liver diseases. Shortage of donors is a major problem in all developed countries and in some, such as Japan, living related donors form the majority of transplant operations. *Indications* include the following:

Acute liver disease. Patients with fulminant hepatic failure of any cause, including acute viral hepatitis ([p. 318](#)).

Chronic liver disease. The indications for transplantation are usually for complications of cirrhosis, no longer responsive to therapy. Timing of the transplant depends on donor availability. All patients with end-stage (Child's grade C) cirrhosis should be referred to a transplant centre and also those with debilitating symptoms. In addition specific extra-hepatic complications of cirrhosis, even with preserved liver function, such as hepatopulmonary syndrome (shunting in the lung leading to hypoxia) and porto-pulmonary hypertension, can be reversed by liver transplantation.

- **Primary biliary cirrhosis.** Patients with this disease should be transplanted when their serum bilirubin is persistently $>100 \mu\text{mol/L}$ or symptoms such as itching are intolerable.
- **Chronic hepatitis B if HBV DNA negative** or levels falling under therapy. Following transplantation, recurrence of hepatitis is prevented by hepatitis B immunoglobulin and nucleoside analogues in combination to prevent escape mutants (see this chapter).
- **Chronic hepatitis C** is the most common indication. Universal HCV reinfection occurs with chronic hepatitis of varying severity and cirrhosis occurs in 10–20% at 5 years. Antiviral agents may delay this progression if sustained viral response occurs.
- **Autoimmune hepatitis.** In patients who have failed to respond to medical treatment or have major side-effects of corticosteroid therapy. It can reoccur.
- **Alcoholic liver disease.** Well-motivated patients who have stopped drinking without improvement of liver disease are offered a transplant, with concomitant and frequent counselling before and after transplant.
- **Primary metabolic disorders.** Examples are Wilson's disease, hereditary haemochromatosis and α_1 -antitrypsin deficiency.
- **Other conditions**, such as primary sclerosing cholangitis (PSC), polycystic liver disease, NASH and metabolic diseases in which the defect is in the liver, e.g. primary oxaluria.

Contraindications

Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine), and if the patient is not psychologically committed.

Relative contraindications are mainly anatomical considerations that would make surgery more difficult, such as extensive splanchnic venous thrombosis. With exceptions, patients aged 70 years or over are not usually transplanted.

In hepatocellular carcinoma the recurrence rate is high unless there are fewer than three small ($<3 \text{ cm}$) lesions or a solitary nodule of $<5 \text{ cm}$.

Preparation for surgery

Pretransplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, radiological demonstration of the hepatic arterial and biliary tree as well as assessment of cardiorespiratory and renal status. Because of the ethical and financial implications of this operation, regular psychosocial support is vital, and psychiatric counselling may be necessary in some cases.

The donor should be ABO compatible (but no HLA matching is necessary) and have no evidence of active sepsis, malignancy, HIV, HBV or HCV infection. Younger donors (<50 years) result in better graft function. The donor liver is cooled and stored on ice; its preservation time can be up to 20 h. The recipient operation takes approximately 8 hours and rarely requires a large blood transfusion, and sometimes none at all. Cadaveric donor livers may consist of whole graft, split grafts (for two recipients) or reduced grafts or from non-heart-beating donors. Live donors may be healthy individuals or patients with, for example, familial amyloid polyneuropathy, whose livers can then be transplanted into others (domino transplant). Right lobe donors have a mortality between 1 in 200 and 1 in 400.

The operative mortality is low. Most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections are still a problem owing to immunosuppression. Various immunosuppressive agents have been used, but microemulsified ciclosporin, tacrolimus in combination with either azathioprine or mycophenolate mofetil, steroids and sirolimus are the most common. A pretransplant serum creatinine above $160 \mu\text{mol/L}$ (2 mg/dL) is the best predictor of post-transplant death.

Rejection

Acute or cellular rejection is usually seen 5–10 days post-transplant; it can be asymptomatic or there may be a fever. Histologically, there is a pleomorphic portal infiltrate with prominent eosinophils, bile duct damage and endothelialitis of the blood vessels. This type of rejection responds to immunosuppressive therapy.

Chronic ductopenic rejection is seen from 6 weeks to 9 months post-transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS) and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection may rarely be reversed by immunosuppression, but often requires retransplantation.

Graft-versus-host disease is extremely rare.

Prognosis

Elective liver transplantation in low-risk patients has a 90% 1-year survival. Five-year survivals are now as high as 70–85%. Patients require lifelong immunosuppression, although the doses can be reduced over time without significant problems. Transplantation for HCV cirrhosis, PSC and HCC, are the major diseases in which long term survival is compromised by disease recurrence.

Complications and effects of cirrhosis

These are shown in [Table 7.12](#).

Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. The pressure within it is

Table 7.12 Complications and effects of cirrhosis

Portal hypertension and gastrointestinal haemorrhage
Ascites
Portosystemic encephalopathy
Hepatocellular carcinoma
Bacteraemias, infections
Renal failure

normally 5–8 mmHg with only a small gradient across the liver to the hepatic vein in which blood is returned to the heart via the inferior vena cava. Portal hypertension can be classified according to the site of obstruction:

- **Prehepatic** – due to blockage of the portal vein before the liver
- **Intrahepatic** – due to distortion of the liver architecture, which can be presinusoidal (e.g. in schistosomiasis) or post-sinusoidal (e.g. in cirrhosis)
- **Post-hepatic** – due to venous blockage outside the liver (rare).

As portal pressure rises above 10–12 mmHg, the compliant venous system dilates and collaterals occur within the systemic venous system. The main sites of the collaterals are at the gastro-oesophageal junction, rectum, left renal vein, diaphragm, retroperitoneum and the anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial in position and tend to rupture. Portosystemic anastomoses at other sites seldom give rise to symptoms. Rectal varices are found frequently (30%) if carefully looked for and can be differentiated from haemorrhoids, which are lower in the anal canal. The microvasculature of the gut becomes congested giving rise to portal hypertensive gastropathy and colopathy, in which there is punctate erythema and sometimes erosions, which can bleed.

Pathophysiology

Portal vascular resistance is increased in chronic liver disease. During liver injury, stellate cells are activated and transform into myofibroblasts. In these cells there is *de novo* expression of the specific smooth muscle protein α -actin. Under the influence of mediators, such as endothelin, nitric oxide or prostaglandins, the contraction of these activated cells contributes to abnormal blood flow patterns and increased resistance to blood flow. In addition the balance of fibrogenic and fibrolytic factors is shifted towards fibrogenesis. This increased resistance leads to portal hypertension and opening of portosystemic anastomoses in both precirrhotic and cirrhotic livers. Neoangiogenesis also occurs. Patients with cirrhosis have a hyperdynamic circulation. This is thought to be due to the release of mediators, such as nitric oxide and glucagon, which leads to peripheral and splanchnic vasodilatation. This effect is followed by plasma volume expansion due to sodium retention (see the discussion on ascites, p. 335), and this has a significant effect in maintaining portal hypertension.

Causes (Table 7.13)

The most common cause is cirrhosis. Other causes include the following.

Prehepatic causes

Extrahepatic blockage is due to portal vein thrombosis. The cause is often unidentified, but some cases are due to portal vein occlusion secondary to congenital portal venous

Table 7.13 Causes of portal hypertension

Prehepatic

Constrictive pericarditis
IVC obstruction

abnormalities or neonatal sepsis of the umbilical vein. Many are due to inherited defects causing prothrombotic conditions, e.g. factor V Leiden.

Patients usually present with bleeding, often at a young age. They have normal liver function and, because of this, their prognosis following bleeding is excellent.

The portal vein blockage can be identified by ultrasound with Doppler imaging; CT and MR angiography are also used.

Treatment for variceal bleeding is usually repeated endoscopic therapy or non-selective beta-blockade. Splenectomy is only performed if there is isolated splenic vein thrombosis. Anticoagulation prevents further thrombosis and intestinal infarction, and does not increase the risk of bleeding and prevents intestinal infarction.

Intrahepatic causes

Although cirrhosis is the most common intrahepatic cause of portal hypertension, there are other causes:

- **Non-cirrhotic portal hypertension.** Patients present with portal hypertension and variceal bleeding but without cirrhosis. Histologically, the liver shows mild portal tract fibrosis. The aetiology is unknown, but arsenic, vinyl chloride, antiretroviral therapy and other toxic agents have been implicated. A similar disease is found frequently in India. The liver lesion does not progress and the prognosis is therefore good.
- **Schistosomiasis** with extensive pipe-stem fibrosis is the commonest cause, but is confined to endemic areas such as Egypt and Brazil. However, often there may be concomitant liver disease such as HCV infection.
- **Other causes** include congenital hepatic fibrosis, nodular regenerative hyperplasia and partial nodular transformation (the last two conditions are rare). They all share the common features of hyperplastic liver cell growth in the form of nodules. A wedge liver biopsy is usually required to establish the diagnosis. In none of these conditions are hormones implicated in aetiology or progression.

Post-hepatic causes

Prolonged severe heart failure with tricuspid incompetence and constrictive pericarditis can both lead to portal hypertension. The Budd–Chiari syndrome is described on page 343.

Clinical features

Patients with portal hypertension are often asymptomatic and the only clinical evidence of portal hypertension is

splenomegaly. Clinical features of chronic liver disease are usually present (see p. 312). Presenting features include:

- Haematemesis or melaena from rupture of gastro-oesophageal varices or portal hypertensive gastropathy
- Ascites
- Encephalopathy
- Breathlessness due to porto-pulmonary hypertension or hepatopulmonary syndrome (rare).

Variceal haemorrhage

Approximately 90% of patients with cirrhosis will develop gastro-oesophageal varices, over 10 years, but only one-third of these will bleed from them. Bleeding is likely to occur with large varices, red signs on varices (diagnosed at endoscopy) and in severe liver disease.

Management

Management can be divided into:

- The active bleeding episode
- The prevention of rebleeding
- Prophylactic measures to prevent the first haemorrhage. Despite all the therapeutic techniques available, the prognosis depends on the severity of the underlying liver disease, with an overall mortality from variceal haemorrhage of 15% to 25%, reaching 50% in Child's grade C.

Initial management of acute variceal bleeding

(Fig. 7.24)

See also the discussion of the general management of gastrointestinal haemorrhage on page 327.

Resuscitation

- Assess the general condition of the patient – pulse and blood pressure.
- Insert an intravenous line and obtain blood for grouping and crossmatching, haemoglobin, PT/INR, urea, electrolytes, creatinine, liver biochemistry and blood cultures.
- Restore blood volume with plasma expanders or, if possible, blood transfusion. These measures are

discussed in more detail in the treatment of shock (p. 886). Prompt correction, but not over-correction, of hypovolaemia is necessary in patients with cirrhosis as their baroreceptor reflexes are diminished. Target haemoglobin only needs to be 80 g/L, as this lessens the likelihood of early rebleeding.

- Ascitic tap.
- Monitor for alcohol withdrawal. Give thiamine i.v.
- Start prophylactic antibiotics – third-generation cephalosporins, e.g. cefotaxime. These treat and prevent infection and early rebleeding and reduce mortality.

Urgent endoscopy

Endoscopy should be performed to confirm the diagnosis of varices. It also excludes bleeding from other sites (e.g. gastric ulceration) or portal hypertensive (or congestive) gastropathy. The latter term is used for chronic gastric congestion, punctate erythema and gastric erosions. It is a source of bleeding but varices may or may not be present. Propranolol (see below) is the best treatment for this gastropathy.

Variceal banding or injection sclerotherapy

Varices can be banded by mounting a band on the tip of the endoscope, sucking the varix just into the end of the scope and dislodging the band over the varix using a trip-wire mechanism. Alternatively, varices can be injected with a sclerosing agent that may arrest bleeding by producing vessel thrombosis. A needle is passed down the biopsy channel of the endoscope and a sclerosing agent is injected into the varices.

Acute variceal banding and sclerotherapy are the treatments of choice; they arrest bleeding in more than 80% of cases and reduce early rebleeding. Between 15% and 20% of bleeding comes from gastric varices and results of sclerotherapy and banding are poor. Injection of tissue glue is preferable.

Other measures available

Vasoconstrictor therapy

The main use of this is for emergency control of bleeding while waiting for endoscopy and in combination with endoscopic techniques. The aim of vasoconstrictor agents is to restrict portal inflow by splanchnic arterial constriction.

- **Terlipressin.** This is the only vasoconstrictor shown to reduce mortality. The dose is 2 mg 6-hourly, reducing to 1 mg 4-hourly after 48 h if a prolonged dosage regimen is used. It should not be given to patients with ischaemic heart disease. The patient will complain of abdominal colic, will defecate and have facial pallor owing to the generalized vasoconstriction.
- **Somatostatin.** This drug has few side-effects. An infusion of 250–500 µg/hour appears to reduce bleeding, but has no effect on mortality. It should be used if there are contraindications to terlipressin.

Balloon tamponade

Balloon tamponade is used mainly to control bleeding if endoscopic therapy or vasoconstrictor therapy has failed or is contraindicated or if there is exsanguinating haemorrhage. The usual balloon tube is a four-lumen Sengstaken-Blakemore, which should be left in place for no more than 12 hours and removed in the endoscopy room prior to the endoscopic procedure. The tube is passed into the stomach and the gastric balloon is inflated with air and pulled back.

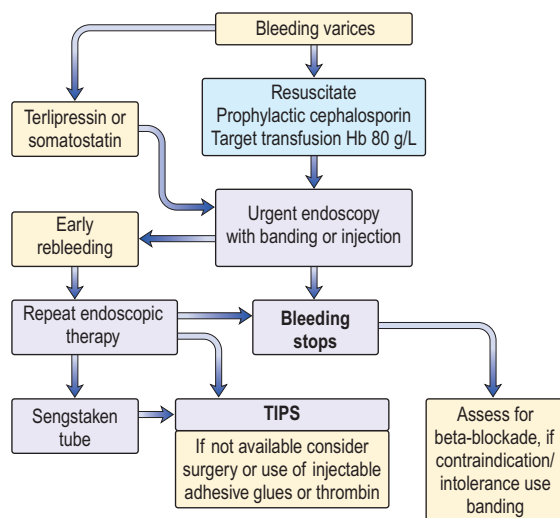

Figure 7.24 Management of gastrointestinal haemorrhage due to oesophageal varices. TIPS, transjugular intrahepatic portosystemic shunt.

Endoscopic pictures of oesophageal varices.

(a) Gross varices. (b) Blood spurting from a varix.

(c) Following a recent bleed.

(d) Varices with a band in place (arrow). (a, c and d Courtesy of Dr Peter Fairclough.)

It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should be inflated only if bleeding is not controlled by the gastric balloon alone.

This technique is successful in up to 90% of patients and is very useful in the first few hours of bleeding. However, it can have serious complications such as aspiration pneumonia, oesophageal rupture and mucosal ulceration, which lead to a 5% mortality. The procedure is very unpleasant for the patient.

A self-expanding covered metal stent with a wire loop to enable removal, introduced orally or endoscopically, can be placed over the varices, is effective and has the advantage that swallowing is not impaired. It is removed 7 days after insertion.

Additional management of acute episode

- **Measures to prevent encephalopathy.** Portosystemic encephalopathy (PSE) can be precipitated by a large bleed (since blood contains protein). The management is described on [page 337](#).
- **Nursing.** Patients require high-dependency/intensive care nursing. They should be nil by mouth until bleeding has stopped.
- **Reduction in acid secretion.** Ranitidine is preferable to proton pump inhibitors as it lessens the risk of *C. difficile* infection. Sucralfate 1 g four times daily can reduce oesophageal ulceration following endoscopic therapy.

Management of an acute rebleed

Rebleeding occurs in about 15–20% within 5 days after a single session of therapeutic endoscopy. The source of rebleeding should be established by endoscopy. It is sometimes due to a sclerotherapy-induced ulcer or slippage of a ligation band. Management starts with repeat endoscopic therapy – once only to control rebleeding (further sessions of sclerotherapy or banding are not advisable).

Transjugular intrahepatic portocaval shunt (TIPS)

TIPS is used when bleeding cannot be stopped or early rebleeding occurs after endoscopic therapy within 5 days. In this technique, a guidewire is passed from the jugular vein into the liver and into the portal vein. After a balloon expansion of the tract between hepatic and portal vein, an expandable covered metal shunt is placed over the wire to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt. There is an increased risk of portal systemic encephalopathy. Recurrent portal hypertension due to stent stenosis or thrombosis is far less frequent with ‘covered’ compared to ‘bare’ stents. Collaterals arising from the splenic or portal veins can be selectively embolized.

Emergency surgery

This is used when other measures fail or if TIPS is not available and, particularly, if the rebleeding is from gastric fundal varices. Oesophageal transection and ligation of the feeding vessels to the bleeding varices is the most common surgical technique. Acute portosystemic shunt surgery (see below) is infrequently performed.

Prevention of recurrent variceal bleeding

The risk of recurrence of bleeding without prophylaxis is 60–80% over a 2-year period with an approximate mortality of 20% per episode.

Long-term measures

Non-selective beta-blockade. Oral propranolol in a dose sufficient to reduce resting pulse rate by 25% has been shown to decrease portal pressure. Portal inflow is reduced by two mechanisms: by a decrease in cardiac output (β_1), and by the blockade of β_2 vasodilator receptors on the splanchnic arteries, leaving an unopposed vasoconstrictor effect. This decreases the frequency of rebleeding, and is as effective as sclerotherapy and ligation as it also prevents bleeding from portal hypertensive gastropathy. It is the treatment of first choice, combined with endoscopic ligation (see below), but a substantial number of patients either have contraindications or are intolerant of beta-blockers. Significant reduction of hepatic venous pressure gradient (HVPG, measured by hepatic vein catheterization) is associated with very low rates or absence of rebleeding, particularly if <12 mmHg. Assessment of HVPG target reduction has prognostic specificity but poor sensitivity and thus poor clinical applicability, and as combined ligation and beta-blockers are the established treatment, monitoring of HVPG is redundant.

Endoscopic treatment. The use of repeated courses of banding at 2-weekly intervals leads to obliteration of varices. This markedly reduces rebleeding, most instances occurring before the varices have been fully obliterated. Between 30% and 40% of varices return per year, so follow-up endoscopy with ablation should be performed. Banding is superior to sclerotherapy, and should be used combined with beta-blockers.

Although a reduction in bleeding episodes occurs, the effect on survival is controversial and probably small. Complications include oesophageal ulceration, mediastinitis and rarely strictures.

Transjugular portosystemic stent shunts. These reduce rebleeding rates compared to endoscopic techniques, but do not improve survival and increase encephalopathy. They are used if endoscopic or medical therapy fails.

Surgical procedures

Surgical portosystemic shunting is associated with an extremely low risk of rebleeding, and is used if TIPS is not available. Hepatic encephalopathy is a significant complication. Operative mortality is low in patients with Child’s grade A (0–5%) but rises with worsening liver disease. The ‘shunts’ performed are usually an end-to-side portocaval anastomosis or a selective distal splenorenal shunt (Warren shunt), which transiently maintains hepatic blood flow via the superior mesenteric vein.

Devascularization procedures including oesophageal transection do not produce encephalopathy, and can be used when there is splanchnic venous thrombosis.

Liver transplantation ([p. 331](#)) is the best option when there is poor liver function.

Prophylactic measures

Patients with cirrhosis and varices that have not bled should be prescribed non-selective beta-blockers (e.g. propranolol or carvedilol). This reduces the chances of upper GI bleeding, may increase survival and is cost-effective. If there are contraindications or intolerance, variceal banding is an option. Beta-blockers do not prevent development of varices.

Ascites

Ascites is fluid within the peritoneal cavity and is a common complication of cirrhosis. The pathogenesis of ascites in liver disease is secondary to renal sodium and water retention. Several factors are involved.

- **Sodium and water retention** results from peripheral arterial vasodilatation and consequent reduction in the effective blood volume. Nitric oxide and other substances (e.g. atrial natriuretic peptide and prostaglandins) act as vasodilators. The reduction in effective blood volume activates various neurohumoral pressor systems such as the sympathetic nervous system and the renin–angiotensin system, thus promoting salt and water retention (see Fig. 13.5).
- **Portal hypertension** exerts a local hydrostatic pressure and leads to increased hepatic and splanchnic production of lymph and transudation of fluid into the peritoneal cavity.
- **Low serum albumin** (a consequence of poor synthetic liver function) may further contribute by a reduction in plasma oncotic pressure.

In patients with ascites, urine sodium excretion rarely exceeds 5 mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30 mmol in 24 hours. The normal daily dietary sodium intake may vary between 120 and 200 mmol, resulting in a positive sodium balance of approximately 90–170 mmol in 24 h (equivalent to 600–1300 mL of fluid retained).

Clinical features

The abdominal swelling associated with ascites develops over many weeks or as rapidly as a few days. Precipitating factors include a high sodium diet or the development of a hepatocellular carcinoma or splanchnic vein thrombosis. Mild generalized abdominal pain and discomfort are common but, if more severe, should raise the suspicion of spontaneous bacterial peritonitis (see below). Respiratory distress accompanies tense ascites, and also causes difficulty in eating.

The presence of fluid is confirmed by demonstrating shifting dullness. Many patients also have peripheral oedema. A pleural effusion (usually on the right side) may infrequently be found and arises from the passage of ascitic fluid through congenital diaphragmatic defects.

Investigations

A diagnostic aspiration of 10–20 mL of fluid should be obtained and the following performed:

- **Cell count.** A neutrophil count above 250 cells/mm³ is indicative of an underlying (usually spontaneous) bacterial peritonitis.
- **Gram stain and culture** – for bacteria and acid-fast bacilli.
- **Protein.** A high serum-ascites albumin gradient of >11 g/L suggests portal hypertension, and a low gradient <11 g/L is associated with abnormalities of the peritoneum, e.g. inflammation, infections, neoplasia (Box 7.4).
- **Cytology** – for malignant cells.
- **Amylase** – to exclude pancreatic ascites.

The differential diagnosis of ascites is listed in Table 7.14.

Management

The aim is to both reduce sodium intake and increase renal excretion of sodium, producing a net reabsorption of fluid from the ascites into the circulating volume. The maximum rate at which ascites can be mobilized is 500–700 mL in 24 h (see below). The management is as follows:

- Check serum electrolytes, creatinine and eGFR at the start and every other day; weigh patient and measure urinary output daily.

Box 7.4 The serum-ascites albumin gradient

High serum-ascites albumin gradient (>11 g/L)

- Portal hypertension, e.g. hepatic cirrhosis
- Hepatic outflow obstruction
- Budd–Chiari syndrome
- Hepatic veno-occlusive disease
- Cardiac ascites
- Tricuspid regurgitation
- Constrictive pericarditis
- Right-sided heart failure

Low serum-ascites albumin gradient (<11 g/L)

- Peritoneal carcinomatosis
- Peritoneal tuberculosis
- Pancreatitis
- Nephrotic syndrome

Table 7.14 Causes of ascites divided according to the type of ascitic fluid

Straw-coloured

Malignancy (most common cause)

Cirrhosis

Infective

Tuberculosis

Following intra-abdominal perforation – any bacterium may be found (e.g. *E. coli*)

Spontaneous in cirrhosis

Hepatic vein obstruction (Budd–Chiari syndrome) protein level high in fluid

Chronic pancreatitis

Congestive cardiac failure

Constrictive pericarditis

Meigs' syndrome (ovarian tumour)

Hypoproteinaemia (e.g. nephrotic syndrome)

Chylous

Obstruction of main lymphatic duct (e.g. by carcinoma) – chylomicrons are present

Cirrhosis

Haemorrhagic

Malignancy

Ruptured ectopic pregnancy

Abdominal trauma

Acute pancreatitis

- Bed rest alone will lead to a diuresis in a small proportion of people by improving renal perfusion, but in practice is not helpful.
- By dietary sodium restriction it is possible to reduce sodium intake to 40 mmol in 24 h and still maintain an adequate protein and calorie intake with a palatable diet.
- Drugs: many contain significant amounts of sodium (up to 50 mmol daily). Examples include antacids, antibiotics (particularly the penicillins and cephalosporins) and effervescent tablets. Sodium-retaining drugs (non-steroidals, corticosteroids) should be avoided.
- Fluid restriction is probably not necessary unless the serum sodium is under 128 mmol/L (see below).
- The diuretic of first choice is the aldosterone antagonist spironolactone, starting at 100 mg daily. Chronic administration produces gynaecomastia. Eplerenone 25 mg once daily does not cause gynaecomastia.

The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss

or 1.0 kg if peripheral oedema is present). Although 60% of patients respond with this regimen, diuresis is often poor and the spironolactone can be increased gradually to 400 mg daily providing there is no hyperkalaemia. A loop diuretic, such as furosemide 20–40 mg or bumetanide 0.5 mg or 1 mg daily, is added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia and volume depletion.

Ascitic fluid is mobilized more slowly than interstitial fluid, and diuretics should be given with great care in those without peripheral oedema.

Diuretics should be temporarily discontinued if a rise in serum creatinine level occurs, representing overdiuresis and hypovolaemia, or if there is hyperkalaemia or the development of precoma. Hyponatraemia occurring during therapy almost always represents haemodilution secondary to a failure to clear free water (usually a marker of reduced renal perfusion) and should be treated by stopping the diuretics if the sodium level falls below approximately 128 mmol/L as well as introducing water restriction. Vaptans (p. 645), a class of drugs that increase free water clearance by inhibition of vasopressin receptors, are being evaluated in cirrhosis.

Paracentesis

This is used to relieve symptomatic tense ascites or when diuretic therapy is insufficient to control accumulation of fluid. The main complication is hypovolaemia and renal dysfunction (post-paracentesis circulatory dysfunction) as the ascites reaccumulates at the expense of the circulating volume; this is more likely with >5 L removal and worse liver function. In patients with normal renal function and without hyponatraemia, this is overcome by infusing albumin (8 g/L of ascitic fluid removed). In practice, up to 20 L can be removed over 4–6 hours, with albumin infusion.

Shunts

A transjugular intrahepatic portosystemic shunt (TIPS) is used for resistant ascites providing there is no spontaneous portosystemic encephalopathy and minimal disturbance of renal function. Frequency of paracentesis and diuretic use is usually reduced and nutrition improves. Survival may improve. The use of a peritoneo-venous shunt has been abandoned in most centres due to a high rate of blockage.

Spontaneous bacterial peritonitis (SBP)

This represents a serious complication of ascites with cirrhosis and occurs in approximately 8%. The infecting organisms gain access to the peritoneum by haematogenous spread; most are *Escherichia coli*, *Klebsiella* or enterococci. The condition should be suspected in any patient with ascites who clinically deteriorates. Features such as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed (see above). A raised neutrophil count in ascites is alone sufficient evidence to start treatment immediately. A third-generation cephalosporin, such as cefotaxime or ceftazidime, is used and is modified on the basis of culture results. Mortality is 10–15%. Recurrence is common (70% within a year) and an oral quinolone, e.g. norfloxacin 400 mg daily, is given for prevention, prolonging the survival. Primary prophylaxis of SBP in patients with ascites protein <10 g/L or severe liver disease also prevents hepatorenal syndrome and improves survival.

SBP is an indication to refer to a liver transplant centre.

Portosystemic encephalopathy (PSE)

This is a chronic neuropsychiatric syndrome secondary to cirrhosis. Acute encephalopathy can occur in acute hepatic

Table 7.15 Factors precipitating portosystemic encephalopathy

High dietary protein
Gastrointestinal haemorrhage
Constipation
Infection, including spontaneous bacterial peritonitis

paracentesis
Drugs (e.g. any CNS depressant)
Portosystemic shunt operations, TIPS
Any surgical procedure
Progressive liver damage
Development of hepatocellular carcinoma

TIPS, transjugular intrahepatic portocaval shunt.

failure (see p. 326). PSE can occur in portal hypertensive patients due to spontaneous 'shunting', or in those with surgical or TIPS shunts. Encephalopathy is potentially reversible.

Pathogenesis

The mechanism is unknown but several factors are involved. In cirrhosis, the portal blood bypasses the liver via the collaterals and the 'toxic' metabolites pass directly to the brain to produce the encephalopathy.

Many 'toxic' substances may be causative factors, principally ammonia, but also free fatty acids, mercaptans and accumulation of false neurotransmitters (octopamine) or activation of the γ -aminobutyric acid (GABA) inhibitory neurotransmitter system. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine and isoleucine) also occur. Ammonia has a major role; ammonia-induced alteration of brain neurotransmitter balance – especially at the astrocyte-neurone interface – is the leading pathophysiological mechanism. Ammonia is produced by intestinal bacteria breaking down protein. The factors precipitating PSE are shown in Table 7.15.

Clinical features

An acute onset often has a precipitating factor (Table 7.15). The patient becomes increasingly drowsy and comatose.

Chronically, there is a disorder of personality, mood and intellect, with a reversal of normal sleep rhythm. These changes may fluctuate, and a history from a relative must be obtained. The patient is irritable, confused, disorientated and has slow slurred speech. General features include nausea, vomiting and weakness. Coma occurs as the encephalopathy becomes more marked, but there is always hyperreflexia and increased tone. Convulsions are so very rare that other causes must be looked for.

Signs include:

- Fetor hepaticus (a sweet smell to the breath)
- A coarse flapping tremor seen when the hands are outstretched and the wrists hyperextended (asterixis)
- Constructional apraxia, with the patient being unable to write or draw, e.g. a five-pointed star
- Decreased mental function, which can be assessed by using the serial-sevens test. A trail-making (or connection) test (the ability to join numbers and letters (in chronological order) with a pen within a certain time – a standard psychological test for brain dysfunction) is prolonged.

Diagnosis is clinical. Routine liver biochemistry merely confirms the presence of liver disease, not the presence of encephalopathy.

Additional investigations

- Electroencephalography (EEG) shows a decrease in the frequency of the normal α -waves (8–13 Hz) to α -waves of 1.5–3 Hz. These changes occur before coma supervenes.
- Visual evoked responses (see p. 1090) also detect subclinical encephalopathy.
- Arterial blood ammonia can be useful for the differential diagnosis of coma and to follow a patient with PSE, but is not readily available.

Management

- Identify and remove the possible precipitating cause, such as drugs with cerebral depressant properties, constipation or electrolyte imbalance due to overdiuresis.
- Give purgation and enemas to empty the bowels of nitrogenous substances. Lactulose (10–30 mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactilol (β -galactoside sorbitol 30 g daily) is metabolized by colonic bacteria and is comparable in efficacy to lactulose.
- Maintain nutrition with adequate calories, given if necessary via a fine-bore nasogastric tube, and do not restrict protein for more than 48 h.
- Give antibiotics. Rifaximin is mainly unabsorbed and well tolerated long term, and prevents further episodes of PSE. Metronidazole (200 mg four times daily) is also effective in the acute situation. Neomycin should be avoided. Stop or reduce diuretic therapy.
- Give intravenous fluids as necessary (beware of too much sodium).
- Treat any infection.
- Increase protein in the diet to the limit of tolerance as the encephalopathy improves.

Course and prognosis

Acute encephalopathy in acute liver failure has a very poor prognosis as the disease itself has a high mortality. In cirrhosis, chronic PSE is very variable and adversely affects prognosis. Very rarely with chronic portosystemic shunting, an organic syndrome with cerebellar signs or choreoathetosis can develop, as well as a myelopathy leading to a spastic paraparesis due to demyelination. Patients should be referred to a liver transplant centre.

Renal failure (hepatorenal syndrome)

The hepatorenal syndrome occurs typically in a patient with advanced cirrhosis, portal hypertension with jaundice and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e. tubular function is intact) and almost normal renal histology. The renal failure is described as 'functional'. It is sometimes precipitated by overvigorous diuretic therapy, NSAIDs, diarrhoea or paracentesis, and infection, particularly spontaneous bacterial peritonitis.

The mechanism is similar to that producing ascites. The initiating factor is thought to be extreme peripheral vasodilatation, possibly due to nitric oxide, leading to an extreme decrease in the effective blood volume and hypotension (p. 305). This activates the homeostatic mechanisms, causing a rise in plasma renin, aldosterone, noradrenaline (norepinephrine) and vasopressin, leading to vasoconstriction of the

renal vasculature. There is an increased preglomerular vascular resistance causing the blood flow to be directed away from the renal cortex. This leads to a reduced glomerular filtration rate and plasma renin remains high. Salt and water retention occur with reabsorption of sodium from the renal tubules. There is also a decrease in cardiac output inappropriate to the degree of systemic vasodilatation, which further exacerbates the haemodynamic abnormalities.

Other mediators have been incriminated in the pathogenesis of the hepatorenal syndrome, in particular the eicosanoids. This has been supported by the precipitation of the syndrome by inhibitors of prostaglandin synthase such as non-steroidal anti-inflammatory drugs (NSAIDs).

Diuretic therapy should be stopped and intravascular hypovolaemia corrected, preferably with albumin. Terlipressin or noradrenaline with intravenous albumin improves renal function in one-third of patients. Liver transplantation is the best option.

Hepatopulmonary syndrome

This is defined as a hypoxaemia occurring in patients with advanced liver disease. It is due to intrapulmonary vascular dilatation with no evidence of primary pulmonary disease. The patients have features of cirrhosis with spider naevi and clubbing as well as cyanosis. Most patients have no respiratory symptoms, but with more severe disease, patients are breathless on standing. Transthoracic ECHO shows intrapulmonary shunting, and arterial blood gases confirm the arterial oxygen desaturation. These changes are improved with liver transplantation.

Porto-pulmonary hypertension

This must be distinguished from the hepatopulmonary syndrome as in this group there is pulmonary hypertension. It occurs in 1–2% of patients with cirrhosis related to portal hypertension. It may respond to medical therapy. Severe pulmonary hypertension is a contraindication for liver transplantation.

Primary hepatocellular carcinoma

This is discussed on page 347.

Types of cirrhosis

Alcoholic cirrhosis

This is discussed in the section on alcoholic liver disease (p. 342).

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a chronic disorder in which there is a progressive destruction of the small bile ducts, eventually leading to cirrhosis. Of those affected, 90% are women in the age range 40–50 years. PBC is frequently being diagnosed in its milder forms. The prevalence is approximately 7.5 per 100 000, with a 1–6% increase in first-degree relatives. PBC has been called 'chronic non-suppurative destructive cholangitis'; this term is more descriptive of the early lesion and emphasizes that true cirrhosis occurs only in the later stages of the disease.

Aetiology

The aetiology is unknown, but immunological mechanisms play a part. Serum anti-mitochondrial antibodies (AMA) are found in almost all patients with PBC, and of the

Hepatocellular carcinoma (H&E) ×25.

mitochondrial proteins involved, the antigen M2 is specific to PBC.

Five M2-specific antigens have been further defined using immunoblot techniques, of which the E2 component of the pyruvate dehydrogenase complex (PDC) is the major M2 autoantigen (72 kDa E2 subunit (PDC, E2)). The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis is unclear. Antibodies against nuclear antigens, e.g. anti gp210, are present in 50% of patients and correlate with progression towards liver failure.

It seems likely that an environmental factor acts on a genetically predisposed host via molecular mimicry initiating autoimmunity. *E. coli* and *N. aromaticivorans* antibodies are present in high titre. Halogenated hydrocarbons mimic the PDC autoepitopes.

Although damage to bile ducts is a feature, antibodies to bile ductules are not specific to PBC. Biliary epithelium from patients with PBC expresses aberrant class II HLAs, but it is not known whether this expression is the cause or result of the inflammatory response. Cell-mediated immunity is impaired (demonstrated both *in vitro* and by skin testing); cytotoxic CD4⁺ and CD8⁺ T lymphocytes directly produce biliary epithelium damage. They recognize the inner lipoyl domain and lipoic acid also recognized by AMA. There is an increased synthesis of IgM, thought to be due to a failure of the switch from IgM to IgG antibody synthesis. No specific associated class II MHC loci have been found.

Clinical features

Asymptomatic patients are discovered on routine examination or screening and may have hepatomegaly, a raised serum alkaline phosphatase or autoantibodies.

Pruritus is often the earliest symptom, preceding jaundice by a few years. Fatigue, which is often disabling, may accompany pruritus, particularly in progressive cases. When jaundice appears, hepatomegaly is usually found. In the later stages, patients are pigmented and jaundiced with severe pruritus. Pigmented xanthelasma on eyelids or other deposits of cholesterol in the creases of the hands are seen.

Associated disorders

Autoimmune disorders (e.g. Sjögren's syndrome, scleroderma, thyroid disease) occur with increased frequency. Keratoconjunctivitis sicca (dry eyes and mouth) is seen in 70% of cases. Renal tubular acidosis, membranous glomerulonephritis, coeliac disease and interstitial pneumonitis are also associated with PBC.

Investigations

- **Mitochondrial antibodies** – measured routinely by ELISA (in titres >1:160) – are present in over 95% of patients; M2 antibody is specific. Other nonspecific antibodies (e.g. anti-nuclear factor and smooth muscle) may also be present.
- **High serum alkaline phosphatase** is often the only abnormality in the liver biochemistry.
- **Serum cholesterol** is raised.
- **Serum IgM** may be very high.
- **Ultrasound** can show a diffuse alteration in liver architecture.
- **Liver biopsy** shows characteristic histological features of a portal tract infiltrate, mainly of lymphocytes and plasma cells: approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is

damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis is seen.

Hepatic granulomas are not specific and are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis, parasitic infestation (e.g. strongyloidiasis) and other conditions.

Differential diagnosis

The classical picture presents little difficulty with diagnosis (high serum alkaline phosphatase and the presence of AMA); this can be confirmed by the characteristic histological features although this is not necessary except in doubtful cases. There is a group of patients with the histological changes of PBC but the serology of autoimmune hepatitis. This has been given the name of autoimmune cholangitis and responds to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound and, if there is doubt about the diagnosis, MRCP (or ERCP) should be performed to make sure that the bile ducts are normal.

Treatment

Ursodeoxycholic acid (10–15 mg/kg) improves bilirubin and aminotransferase levels. It should be given early in the asymptomatic phase. It is not clear if prognosis is altered. Symptoms are not improved. Steroids improve biochemical and histological disease but may lead to increased osteoporosis and other side-effects and should not be used.

Malabsorption of fat-soluble vitamins (A, D and K) occurs and supplementation is required when deficiency is detected and prophylactically in the jaundiced patient. Bisphosphonates are required for osteoporosis. Despite raised serum lipid concentrations there is no increased risk from cardiovascular disease, although this has been disputed by one group.

Pruritus is difficult to control, but cholestyramine, one 4 g sachet three times daily, can be helpful, although it is unpalatable. Rifampicin, naloxone hydrochloride and naltrexone (opioid antagonists) have been shown to be of benefit. Intractable pruritus can be relieved by plasmapheresis or a molecular absorbent recirculating system (MARS).

The lack of effective medical therapy has made PBC a major indication for liver transplantation (p. 331).

Complications

The complications are those of cirrhosis. In addition, osteoporosis, and rarely osteomalacia and a polyneuropathy can also occur.

Course and prognosis

This is very variable. Asymptomatic patients and those presenting with pruritus will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly progressive course and die of liver failure or bleeding varices in approximately 5 years. Liver transplantation should therefore be offered when the serum bilirubin is persistently above 100 µmol/L. Transplantation has a 5-year survival of at least 80%.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of patients, PSC is associated with inflammatory bowel disease (usually ulcerative colitis) and it is not unusual for the PSC to

predate the onset of the inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA A1-B8-DR3 haplotype. The autoantibody pANCA (anti-neutrophil cytoplasmic antibody) is found in the serum of 60% of cases. Seventy per cent of patients are men and the average age of onset is approximately 40 years. Secondary PSC is seen in patients with HIV and cryptosporidium (p. 189).

Clinical features

With increasing screening of patients with inflammatory bowel disease PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum alkaline phosphatase. Symptomatic presentation is usually with fluctuating pruritus, jaundice and cholangitis.

Diagnosis

The typical biliary changes associated with PSC may be identified by MRCP. This technique may fail to identify minor, but still clinically significant, intrahepatic duct abnormalities and this may require endoscopic retrograde cholangiography (ERC). The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (Fig. 7.25).

Pathology

Histology can be contributory: it shows inflammation of the intrahepatic biliary radicles with associated scar tissue classically described as being onion skin in appearance. These changes range from minor inflammatory infiltrates to the level of established cirrhosis. The presence of cirrhosis has prognostic implications.

Management

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), ultimately leading to liver cirrhosis

and associated decompensation. Recurrent cholangitis may be a feature before the onset of cirrhosis. Cholangiocarcinoma occurs in up to 15% of patients.

The only proven treatment is liver transplantation. The bile acid ursodeoxycholic acid has been evaluated extensively in the treatment of PSC, but there is no evidence of long-term symptomatic, histological or survival benefit. High-dose therapy (30 mg/kg) may be deleterious. In a small minority of patients with PSC the dominant lesion is of the extrahepatic ducts. Such lesions may be amenable to endoscopic biliary intervention with balloon dilatation and temporary stent placement (p. 357).

Secondary biliary cirrhosis

Cirrhosis can result from prolonged (for months) large duct biliary obstruction. Causes include bile duct strictures, gallstones and sclerosing cholangitis. An ultrasound examination, followed by ERCP or PTC, is performed to outline the ducts and any remedial cause is treated.

Hereditary haemochromatosis

(see also p. 310)

Hereditary haemochromatosis (HH) is an inherited disease characterized by excess iron deposition in various organs leading to eventual fibrosis and functional organ failure. There are four main types of inherited disorders:

- Type 1 HFE. The **HFE** gene (mutation C282Y): commonest on chromosome 6
- Type 2A. Juvenile **HJV** gene (mutation G320V)
- Type 2B. Juvenile **HAMP** gene (mutation 93delG)
- Type 3 TfR2. **TfR2** gene (mutation Y250X)
- Type 4 ferroportin. **SLC40A1** gene (mutation V162del).

All are transmitted by an autosomal recessive gene, apart from the ferroportin iron overload which is dominantly transmitted.

Prevalence and aetiology

HH has a prevalence in Caucasians of homozygotes (affected) of 1 in 400, but very variable phenotypic expression and a heterozygote (carrier) frequency of 1 in 10. It is the most common single gene disorder in Caucasians.

Between 85% and 90% of patients with overt HH are homozygous for the Cys 282 Tyr (C282Y mutation), i.e. type 1 HFE. A second mutation (His 63 Asp, H63D) occurs in about 25% of the population and is in complete linkage disequilibrium with Cys 282 Tyr.

Another form of haemochromatosis (type 3) occurs in Southern Europe and is associated with TfR2, a transferrin receptor isoform. The other types, ferroportin related (type 4) and juvenile forms (types 2A and 2B), are much rarer.

Dietary intakes of iron and chelating agents (ascorbic acid) may be relevant. Iron overload may be present in alcoholics, but alcohol excess *per se* does not cause HH although there is a history of excess alcohol intake in 25% of patients.

Mechanism of damage. This is still unclear. The HFE gene protein interacts with the transferrin receptor 1, which is a mediator in intestinal iron absorption (see Fig. 8.8). Iron is taken up by the mucosal cells inappropriately, exceeding the binding capacity of transferrin.

Hepcidin, a protein synthesized in the liver (Fig. 7.26), is central to the control of iron absorption; it is increased in iron deficiency states and decreased with iron overload. The mutations described above disrupt hepcidin expression,

Figure 7.25 Primary sclerosing cholangitis. An endoscopic cholangiogram showing the typical features of primary sclerosing cholangitis. There are calibre irregularities of the intrahepatic ducts (IHD). There is also minor stricturing of the extrahepatic ducts at the confluence between the common bile duct (CBD) and the common hepatic duct (CHD).

Bacon BR, Adams PC, Kowdley KV et al. Diagnosis and management of hemochromatosis: 2011 Practice Guideline by the American Association for the Study of Liver Diseases. *Hepatology* 2011; 54:328–343.

Figure 7.26 The circulation of iron from the duodenal enterocyte to and from the liver, red cells and the reticuloendothelial macrophages. 1–2 g of iron is absorbed from the intestine (Fig. 8.8, p. 378) and circulates bound to transferrin. The reticuloendothelial cells clear old erythrocytes and release iron to circulate and be stored as ferritin in the liver. The liver is the major site of production of the peptide hormone hepcidin. Hepcidin blocks release of iron from the erythrocytes and macrophages by degrading the iron exporter transferrin. Fe, iron. (Modified from Fleming RE, Ponka P. Iron overload in human disease. *N Engl J Med* 2012; 366:348–359, with permission.)

thereby internalizing ferroportin leading to uninhibited iron overload.

Hepatic expression of the hepcidin gene is decreased in HFE haemochromatosis, facilitating liver iron overload. Excess iron is then taken up by the liver and other tissues gradually over a long period. It seems likely that it is the iron itself that precipitates fibrosis.

Pathology

In symptomatic patients the total body iron content is 20–40 g, compared with 3–4 g in a normal person. The iron content is particularly increased in the liver and pancreas (50–100 times normal) but is also increased in other organs (e.g. the endocrine glands, heart and skin).

In established cases the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells and connective tissue. Cirrhosis is a late feature.

Clinical features

The course of the disease depends on a number of factors, including gender, dietary iron intake, presence of associated hepatotoxins (especially alcohol) and genotypes. Overt clinical manifestations occur more frequently in men; the reduced incidence in women is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the 5th decade. The classic triad of bronze skin pigmentation (due to melanin deposition), hepatomegaly and diabetes mellitus is only present in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found, but symptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are

common, especially in younger patients. Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis) leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

Complications

Of people with cirrhosis, 30% will develop primary hepatocellular carcinoma (HCC). HCC has only very rarely been described in non-cirrhotic patients in whom the excess iron stores have been removed. Early diagnosis is vital.

Investigations

Homozygotes

- **Serum iron** is elevated ($>30 \mu\text{mol/L}$) in 90% with a reduction in the TIBC and a transferrin saturation of $>45\%$.
- **Serum ferritin** is elevated (usually $>500 \mu\text{g/L}$ or 240 nmol/L).
- **Liver biochemistry** is often normal, even with established cirrhosis.

Heterozygotes

Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation ($>45\%$) or serum ferritin (usually $>400 \mu\text{g/L}$).

Genetic testing

If iron studies are abnormal, genetic testing is performed.

Liver biopsy

This is not required for diagnosis, but is useful to assess the extent of tissue damage, assess tissue iron, and measure the hepatic iron concentration ($>180 \mu\text{mol/g}$ dry weight of liver indicates haemochromatosis).

Mild degrees of parenchymal iron deposition in patients with other forms of cirrhosis, particularly due to alcohol, can often cause confusion with true homozygous HH.

Magnetic resonance imaging

MRI shows dramatic reduction in the signal intensity of the liver and pancreas owing to the paramagnetic effect of ferritin and haemosiderin. A highly T2-weighted gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload ($>60 \mu\text{mol/g}$ of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the pancreas is spared, enabling distinction between these two conditions.

Treatment and management

Venesection

This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice-weekly for up to 2 years, i.e. 160 units with 250 mg of iron per unit, equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent reaccumulation of iron. Serum ferritin should remain within the normal range.

Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is often helpful.

Cirrhotic nodule in haemochromatosis showing iron overload (blue) (Perls, $\times 25$).

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferrioxamine, either intermittently or continuously by infusion, has been successful in removing iron.

Screening

In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. *HFE* mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, the serum iron and transferrin saturation are the best and cheapest tests available.

Wilson's disease (progressive hepatolenticular degeneration)

Dietary copper is normally absorbed from the stomach and upper small intestine. Copper is transported to the liver loosely bound to albumin where it is incorporated into apoc caeruloplasmin forming caeruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. The remaining copper is normally excreted in the bile and excreted in faeces.

Wilson's disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain and the cornea. It is potentially treatable and all young patients with liver disease must be screened for this condition.

Aetiology

It is an autosomal recessive disorder with a molecular defect within a copper-transporting ATPase encoded by a gene (designated *ATP7B*) located on chromosome 13, affecting between 1 in 30 000 and 1 in 100 000 individuals. Over 300 mutations have been identified, the most frequent being His 1069 Gly (H1069Q) found in approximately 50% of Caucasian patients, with compound heterozygotes being frequent. This mutation is rare in India and Asia. Wilson's disease occurs worldwide, particularly in countries where consanguinity is common. There is a failure of both incorporation of copper into procaeruloplasmin, which leads to low serum caeruloplasmin, and biliary excretion of copper. There is a low serum caeruloplasmin in over 80% of patients but this is not the cause of the copper deposition. The precise mechanism for the failure of copper excretion is not known.

Pathology

The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see below). The basal ganglia are damaged and show cavitation, the kidneys show tubular degeneration, and erosions are seen in bones.

Clinical features

Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children, which can go on to fulminant hepatic failure, to chronic hepatitis or cirrhosis.

Typical signs are of chronic liver disease with neurological signs of basal ganglia involvement (p. 1082). A specific sign is the Kayser–Fleischer ring, which is due to copper deposition in Descemet's membrane in the cornea. It appears as a greenish brown pigment at the corneal junction and

frequently requires slit-lamp examination for identification. It may be absent in young children.

Investigations

- **Serum copper and caeruloplasmin** are usually reduced but can be normal.
- **Urinary copper** is usually increased 100–1000 µg in 24 h (1.6–16 µmol); normal levels <40 µg (0.6 µmol).
- **Liver biopsy.** The diagnosis depends on measurement of the amount of copper in the liver (>250 µg/g dry weight), although high levels of copper are also found in the liver in chronic cholestasis.
- **Haemolysis and anaemia** may be present.
- **Genetic analysis** is limited but selected exons are screened according to population group.

Treatment

Lifetime treatment with penicillamine, 1–1.5 g daily, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urine copper levels should be monitored and the drug dose adjusted downwards after 2–3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia, skin changes and renal damage. Trientine (1.2–1.8 g/day) and zinc acetate (150 mg/day) have been used as maintenance therapy and for asymptomatic cases. All siblings and children of patients should be screened (*ATP7B* mutation analysis is useful) and treatment given even in the asymptomatic if there is evidence of copper accumulation.

Prognosis

Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Fulminant hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

α_1 -Antitrypsin deficiency

A deficiency of α_1 -antitrypsin (α_1 -AT) (see also p. 793) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). α_1 -AT is a glycoprotein, part of a family of serine protease inhibitors, or serpin superfamily. α_1 -AT deficiency is a genetic disorder and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52 kDa acute-phase protein that is synthesized in the liver and constitutes 90% of the serum α_1 -globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of α_1 -AT are characterized by their electrophoretic mobilities as medium (M), slow (S) or very slow (Z). The normal genotype is protease inhibitor MM (PiMM), the homozygote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein-protein interactions occur between the reactive centre loop of one molecule and the β -pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that the failure of secretion of the abnormal protein leads to an accumulation in the liver, causing liver damage.

Clinical features

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10–15% of adult patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g. PiSZ or PiMZ) may develop liver disease, but the risk is small.

Investigations

- **Serum α_1 -antitrypsin** is low, at 10% of the normal level in the PiZZ phenotypes, and 60% of normal in the S variant.

Histologically, periodic acid-Schiff (PAS)-positive, diastase-resistant globules which contain α_1 -AT are seen in periportal hepatocytes. Fibrosis and cirrhosis can be present.

Treatment

There is no treatment apart from dealing with the complications of liver disease. Patients with hepatic decompensation should be assessed for liver transplantation. Patients should stop smoking (see p. 317).

ALCOHOLIC LIVER DISEASE

This section gives the pathology and clinical features of alcoholic liver disease. The amounts needed to produce liver damage, alcohol metabolism, and other clinical effects of alcohol are described on page 328.

Ethanol is metabolized in the liver by two pathways, resulting in an increase in the NADH/NAD ratio. The altered redox potential results in increased hepatic fatty acid synthesis with decreased fatty acid oxidation, both events leading to hepatic accumulation of fatty acid that is then esterified to glycerides.

The changes in oxidation-reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus typical of alcohol damage. Tumour necrosis factor- α (TNF- α) release from Kupffer cells leads to the release of reactive oxygen species, leading in turn to tissue injury and fibrosis.

Acetaldehyde is formed by the oxidation of ethanol, and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10–20% of people who drink heavily will develop cirrhosis, a genetic predisposition is recognized. Immunological mechanisms have also been proposed, with the release of cytokines, particularly IL-8, which is a neutrophil chemoattractant; infiltration with neutrophils is a feature of alcoholic hepatitis.

Alcohol can enhance the effects of toxic metabolites of drugs (e.g. paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS) (p. 808).

Pathology

Alcohol can produce a wide spectrum of liver disease from fatty change to hepatitis and cirrhosis.

Fatty change

The metabolism of alcohol invariably produces fat in the liver, mainly in zone 3. This is minimal with small amounts of

alcohol, but with larger amounts the cells become swollen with fat (steatosis). There is no liver cell damage. The fat disappears on stopping alcohol. Steatosis is also seen in non-alcoholic fatty liver disease (p. 328).

In some cases collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can sometimes progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells (p. 328).

Alcoholic hepatitis

In addition to fatty change there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage as they can be found in other liver disease, such as Wilson's disease and PBC. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis

This is classically of the micronodular type, but a mixed pattern is also seen accompanying fatty change, and evidence of pre-existing alcoholic hepatitis may be present.

Clinical features

Fatty liver

There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur together with other features of chronic liver disease.

Alcoholic hepatitis

The clinical features vary in degree:

- The patient may be well, with few symptoms, the hepatitis only being apparent on the liver biopsy in addition to fatty change.
- Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver biochemistry is deranged and the diagnosis is made on liver histology.
- In the severe case, often superimposed on alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present, with a high fever associated with the liver necrosis. On examination, there is deep jaundice, hepatomegaly, sometimes splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis

This represents the final stage of liver disease from alcohol use. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease. The diagnosis is confirmed by liver biopsy.

The patient usually presents with one of the complications of cirrhosis. In many cases, there are features of alcohol dependency (see p. 1182), as well as evidence of involvement of other systems, such as polyneuropathy.

Investigations

Fatty liver

An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both

Liver steatosis (×10).

serum aminotransferase enzymes. The γ -GT level is a useful test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur. Ultrasound or CT will demonstrate fatty infiltration, as will liver histology. Elastography can be used to estimate the degree of fibrosis.

Alcoholic hepatitis

Investigations show a leucocytosis with markedly deranged liver biochemistry with elevated:

- serum bilirubin
- serum AST and ALT
- serum alkaline phosphatase
- prothrombin time (PT).

A low serum albumin may also be found. Rarely, hyperlipidaemia with haemolysis (Zieve's syndrome) may occur.

Liver biopsy, if required, is performed by the transjugular route because of prolonged PT.

Alcoholic cirrhosis

Investigations are as for cirrhosis in general.

Management and prognosis

General management

All patients should stop drinking alcohol. Delirium tremens (a withdrawal symptom) is treated with diazepam. Intravenous thiamine should be given empirically to prevent Wernicke–Korsakoff encephalopathy. Bed rest with a diet high in protein and vitamin supplements is given. Dietary protein sometimes needs to be limited because of encephalopathy. Patients need to be advised to participate in alcohol cessation programmes. The likelihood of abstinence is dependent on many factors, particularly social and family ones.

Fatty liver

The patient is advised to stop drinking alcohol; the fat will disappear and the liver biochemistry usually returns to normal. Small amounts of alcohol can be drunk subsequently as long as patients are aware of the problems and can control their consumption.

Alcoholic hepatitis

In severe cases, the patient requires admission to hospital. Nutrition must be maintained with enteral feeding if necessary and vitamin supplementation given. Steroid therapy does improve short-term outcome in more severe cases as defined by a number of indices. Adding acetylcysteine shows short-term benefits.

Discriminant function (DF)

DF = $[4.6 \times \text{prothrombin time above control in seconds}] + \text{bilirubin (mg/dL)}$

Bilirubin $\mu\text{mol/L} \div 17$ to convert to mg/dL

Severe = >32

The response to steroid therapy can also be evaluated by the Lille score (>0.45 indicates poor response to steroids, which can therefore be stopped) and the Glasgow score (Box 7.5). A Glasgow score >9 indicates steroids are necessary because at >9 the 28-day mortality is 75%, while at <9 it is 50%. The MELD score (p. 329) is also used, but does not indicate which patients need steroid therapy.

Infection must be excluded or concomitantly treated. Treatment for encephalopathy and ascites is commenced. Antifungal prophylaxis should also be used.

Patients are advised to stop drinking for life, as this is undoubtedly a precirrhotic condition. The prognosis is

Box 7.5 Prognostic scores used in the assessment of alcoholic hepatitis and response to corticosteroids

Glasgow alcoholic hepatitis score

Score	1	2	3
Age	<50	>50	
WCC ($\times 10^9/\text{L}$)	<15	>15	
Urea (nmol/L)	<5	>5	
Bilirubin ($\mu\text{mol/L}$)	<125	125–250	>250
INR	<1.5	1.5–2.0	>2.0

Poor prognosis = total score >9 .

Lille score (calculator on www.lillemodel.com)

$R = 3.19 - (0.101 \times \text{age in years}) + (0.147 \times \text{albumin on admission in g/L}) + (0.0165 \times \text{change in bilirubin level from day 0 to day 7 in } \mu\text{mol/L}) - (0.206 \times \text{renal insufficiency [0 if absent, 1 if present]}) - (0.0065 \times \text{bilirubin day 0 in } \mu\text{mol/L}) - (0.0096 \times \text{INR})$

<0.16 indicates a 96% chance of survival at 28 days;

≥ 0.56 indicates a 55% chance of survival at 28 days.

Score = $\text{EXP}(-R) / [1 + \text{EXP}(-R)]$

INR, international normalized ratio; WCC, white cell count.

^aCreatinine $>115 \mu\text{mol/L}$.

variable and, despite abstinence, the liver disease is progressive in many patients.

In severe cases the mortality is at least 50%, and with a PT twice the normal, progressive encephalopathy and acute kidney injury, the mortality approaches 90%. Early transplantation for patients with severe alcoholic hepatitis has a survival rate of 78% compared with 32% of those not transplanted. Unfortunately many return to drinking.

Alcoholic cirrhosis

The management of cirrhosis is described on page 330. Again, all patients are advised to stop drinking for life. Abstinence from alcohol results in an improvement in prognosis, with a 5-year survival of 90%, but with continued drinking this falls to 60%. With advanced disease (i.e. jaundice, ascites and haematemesis) the 5-year survival rate falls to 35%, with most of the deaths occurring in the first year. Liver transplantation results in good survival – recurrence of cirrhosis due to recidivism is rare. Patients often sign a contract with their clinicians regarding their abstinence, both before and after transplantation.

A trial of abstinence to establish if liver disease can improve is mandatory, but transplantation should not be denied if the patient continues to deteriorate. Specific follow-up regarding alcohol use is recommended.

Hepatocellular carcinoma is a complication, particularly in men.

BUDD–CHIARI SYNDROME

In this condition, there is obstruction to the venous outflow of the liver owing to occlusion of the hepatic vein. In one-third of patients the cause is unknown, but specific causes include hypercoagulability states (e.g. paroxysmal nocturnal haemoglobinuria, polycythaemia vera) or thrombophilia (p. 424), taking the contraceptive pill, or leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, hepatocellular carcinoma, hepatic infections (e.g. hydatid cyst), congenital venous webs, radiotherapy or trauma to the liver.

Alcoholic liver disease

Budd–Chiari syndrome

Lucy M et al. Alcoholic hepatitis. *N Engl J Med* 2009; 360:2758–2769.

FURTHER READING

Mathurin P, O'Grady J, Carithers JL et al. Corticosteroids improve short term survival in patients with severe alcoholic hepatitis: meta-analysis of individual patient data. *Gut* 2011; 60:255–266.

The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly and ascites (a fulminant form occurs particularly in pregnant women). In the chronic form there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflux, and splenomegaly with portal hypertension.

Investigations

Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrilobular congestion, haemorrhage, fibrosis and cirrhosis. Ultrasound, CT or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast enhancement. The caudate lobe is spared because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or colour Doppler is useful as they show abnormalities of flow in the hepatic vein. Thrombophilia screening is mandatory. Multiple defects of coagulation are found. Thrombosis of the portal vein is present in 2% of patients.

Differential diagnosis

A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure or constrictive pericarditis, and appropriate investigations should be performed.

Treatment

In the acute situation, thrombolytic therapy can be given. Ascites should be treated, as should any underlying cause (e.g. polycythaemia). Congenital webs should be treated radiologically or resected surgically. A transjugular intrahepatic portosystemic shunt (TIPS) is the first treatment of choice as caval compression does not prejudice the efficacy of TIPS. Surgical portocaval shunts are reserved for those who fail this treatment providing there is no caval obstruction or severe caval compression when a caval stent can be inserted. Liver transplantation is the treatment of choice for chronic Budd–Chiari syndrome and for the fulminant form. Lifelong anticoagulation is mandatory following TIPS and transplantation.

Prognosis

The prognosis depends on the aetiology, but some patients can survive for several years.

HEPATIC SINUSOIDAL OBSTRUCTION SYNDROME (SOS), PREVIOUSLY KNOWN AS VENO-OCCLUSIVE DISEASE

This is due to injury of the hepatic veins and presents clinically like the Budd–Chiari syndrome. It was originally described in Jamaica, where the ingestion of toxic pyrrolizidine alkaloids in bush tea (made from plants of the genera *Senecio*, *Heliotropium* and *Crotalaria*) caused damage to the hepatic veins. It can be seen in other parts of the world. It is also seen as a complication of chemotherapy and total body irradiation before allogeneic bone marrow transplantation. The development of SOS after transplantation carries a high mortality. Treatment is supportive with control of ascites and hepatocellular failure. Transjugular intrahepatic portosystemic shunting (TIPS) has been used in a few cases. Defibrotide is used prophylactically before bone marrow transplantation.

FIBROPOLYCYSTIC DISEASES

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney and occasionally the pancreas, and other organs.

Polycystic disease of the liver

Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (p. 632). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

Solitary cysts

These are usually found by chance during imaging and are mainly asymptomatic.

Congenital hepatic fibrosis

In this rare condition the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. It is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices or a portocaval anastomosis because of their good liver function.

Congenital intrahepatic biliary dilatation (Caroli's disease)

In this rare, non-familial disease there are saccular dilatations of the intrahepatic or extrahepatic ducts. It can present at any age (although usually in childhood) with fever, abdominal pain and recurrent attacks of cholangitis with Gram-negative septicaemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, PTC, ERCP or MRCP. There is an increased risk of biliary malignancy.

LIVER ABSCESS

Pyogenic abscess

These abscesses are uncommon, but may be single or multiple. The most common was a portal pyaemia from intra-abdominal sepsis (e.g. appendicitis or perforations), but now in many cases the aetiology is not known. In the elderly, biliary sepsis is a common cause. Other causes include trauma, bacteraemia and direct extension from, for example, a perinephric abscess.

The organism found most commonly is *E. coli*. *Streptococcus milleri* and anaerobic organisms such as *Bacteroides* are often seen. Other organisms include *Enterococcus faecalis*, *Proteus vulgaris* and *Staphylococcus aureus*. Often the infection is mixed.

Clinical features

Some patients are not acutely ill and present with malaise lasting several days or even months. Others can present with

FURTHER READING

Senzolo M, Cholongitas E, Patch D et al. Update on the classification, assessment, prognosis and therapy of Budd–Chiari syndrome. *Nat Clin Pract Gastroenterol Hepatol* 2005; 2: 182–190.

fever, rigors, anorexia, vomiting, weight loss and abdominal pain. In these patients a Gram-negative septicaemia with shock can occur. On examination there may be little to find. Alternatively, the patient may be toxic, febrile and jaundiced. In such patients, the liver is tender and enlarged and there may be signs of a pleural effusion or a pleural rub in the right lower chest.

Investigations

Patients who are not acutely ill are often investigated as a 'pyrexia of unknown origin' (PUO) and most investigations will be normal. Often the only clue to the diagnosis is a raised serum alkaline phosphatase.

- **Serum bilirubin** is raised in 25% of cases.
- **Normochromic normocytic anaemia** may occur, usually accompanied by a polymorphonuclear leucocytosis.
- **Serum alkaline phosphatase, ESR and CRP** are often raised.
- **Serum B₁₂** is very high, as vitamin B₁₂ is stored in and subsequently released from the liver.
- **Blood cultures** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions. A chest X-ray will show elevation of the right hemidiaphragm with a pleural effusion in the severe case. Depending on age, imaging of the colon may be necessary to find the source of the infection.

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover Gram-positive, Gram-negative and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must also be treated.

Prognosis

The overall mortality depends on the nature of the underlying pathology and has been reduced to approximately 16% with needle aspiration and antibiotics. A unilocular abscess in the right lobe has the better prognosis. Scattered multiple abscesses have a very high mortality, with only one in five patients surviving.

Amoebic abscess

This condition (see also Chapter 4) occurs worldwide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (p. 150) can be carried from the bowel to the liver in the portal venous system leading to portal inflammation, with the development of multiple micro-abscesses and eventually single or multiple large abscesses.

Clinically, the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss and malaise. There is often no history of dysentery. On examination the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

Investigations

These are as for pyogenic abscess, plus:

- Serological tests for amoeba (e.g. haemagglutination, amoebic complement fixation test, ELISA). These

are always positive, particularly if there are bowel symptoms, and remain positive after a clinical cure and therefore do not indicate current disease. A repeat negative test, however, is good evidence against an amoebic abscess.

- Diagnostic aspiration of fluid looking like anchovy sauce.

Treatment

Metronidazole 800 mg three times daily is given for 10 days. Aspiration is used in patients failing to respond, in multiple and sometimes large abscesses, and in those with abscesses in the left lobe of the liver or impending rupture.

Complications

Complications include rupture, secondary infection and septicaemia.

OTHER INFECTIONS OF THE LIVER

Schistosomiasis

Schistosoma mansoni and *S. japonicum* affect the liver, but *S. haematobium* rarely does so (see also p. 157). During their life cycle, the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis and inflammation but not cirrhosis.

Clinically there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni*. In Egypt, there is frequently concomitant chronic hepatitis C infection.

Investigations show a raised serum alkaline phosphatase and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often have false results and may also be positive because of past infection.

Treatment is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension, characteristically pre-sinusoidal due to intense portal fibrosis.

Hydatid disease

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts (see also p. 160).

Clinically, there may be no symptoms or a dull ache and swelling in the right hypochondrium. Investigations show a peripheral eosinophilia in 30% of cases and usually a positive hydatid complement fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (Fig. 7.27).

Medical treatment (e.g. with albendazole 10 mg/kg, which penetrates into large cysts) results in cysts becoming smaller. Puncture, aspiration, injection, reaspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact if possible after first sterilizing the cyst with alcohol, saline or cetrimide. Chronic calcified cysts can be left but

Hepatic sinusoidal obstruction syndrome (SOS), previously known as veno-occlusive disease

Fibropolycystic diseases

Liver abscess

Other infections of the liver

Figure 7.27 CT scan of liver showing a large hydatid cyst (arrow) with 'daughter' cysts lying within it.

there have been no well-designed clinical trials for any therapy.

Complications include rupture into the biliary tree, other organs or intraperitoneally, with spread of infection. The prognosis without any complications is good, although there is always the risk of rupture. Preventative measures include deworming of pet dogs and prevention of pets from eating infected carcasses, as well as veterinary control programmes.

Echinococcus multilocularis causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis enables radical surgery and then continued chemosuppression.

Acquired immunodeficiency syndrome

The liver is often involved and is a significant cause of morbidity or mortality. HIV (see also p. 190) itself is not the cause of the liver abnormalities. Clinical hepatomegaly is common (60% of patients). The following are seen, although less frequently in areas where highly active antiretroviral therapy (HAART) is available:

- Pre-existing/coincidental viral hepatitis – the hepatitis progresses more rapidly (HBV, HCV, HDV) and is a leading cause of death
- Neoplasia: Kaposi's sarcoma and non-Hodgkin's lymphoma – increased risk of HCC
- Opportunistic infection (e.g. *Mycobacterium tuberculosis*, *M. avium-intracellulare*, *Cryptococcus*, *Candida albicans*, toxoplasmosis)
- Drug hepatotoxicity
- Secondary sclerosing cholangitis (see p. 189)
- Non-cirrhotic portal hypertension associated with antiretroviral therapy.

Clinical hepatomegaly is common (60% of patients).

LIVER DISEASE IN PREGNANCY

Liver function is not impaired in pregnancy. Any liver disease from whatever cause can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease, but it is uncommon for women with advanced liver disease to conceive.

The following changes take place:

- Plasma and blood volumes increase during pregnancy but the hepatic blood flow remains constant.
- The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in late pregnancy; drug metabolism can thus be affected.
- The size of the liver remains constant.
- Liver biochemistry remains unchanged apart from a rise in serum alkaline phosphatase from the placenta (up to three to four times) and a decrease in total protein owing to increased plasma volume.
- Triglycerides and cholesterol levels rise, and caeruloplasmin, transferrin, α_1 -antitrypsin and fibrinogen levels are elevated owing to increased hepatic synthesis.
- Postpartum there is a tendency to hypercoagulability, and acute Budd–Chiari syndrome can occur.

There are a number of liver diseases that complicate pregnancy.

Hyperemesis gravidarum

Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy

This condition of unknown aetiology presents usually with pruritus alone in the third trimester. It has a familial tendency and there is a higher prevalence in Scandinavia, Chile and Bolivia.

Liver biochemistry shows a cholestatic picture with high serum ALP (up to four times normal) and raised aminotransferases which occasionally can be very high. The serum bilirubin is slightly raised with jaundice in 60% of cases. Liver biopsy is not indicated but would show centrilobular cholestasis.

Treatment is symptomatic with ursodeoxycholic acid 15 mg/kg daily. Prognosis is usually excellent for the mother but there is increased fetal loss. The condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Pre-eclampsia and eclampsia

Pre-eclampsia is characterized by hypertension, proteinuria and oedema occurring in the second or third trimester. Eclampsia is marked by seizures or coma in addition. Hepatic complications include subcapsular haematoma and infarction, and occasionally fulminant hepatic failure. The HELLP syndrome – a combination of haemolysis, elevated liver enzymes and a low platelet count – can occur in association with severe pre-eclampsia. In the HELLP syndrome, there is epigastric pain, nausea and vomiting, with jaundice in 5% of patients. Delivery is the best treatment for eclampsia.

Acute fatty liver of pregnancy (AFLP)

This is a rare, serious condition of unknown aetiology. There is an association between acute fatty liver and long-chain 3-hydroxyacyl-CoA-dihydroxyl (LCHAD) deficiency. The mechanism is unclear, but abnormal fatty acid metabolites produced by the homozygous or heterozygous fetus enter the circulation and overcome maternal hepatic mitochondrial oxidation systems in a heterozygote mother. It presents in the last trimester with symptoms of fulminant hepatitis –

jaundice, vomiting, abdominal pain, and occasionally haematemesis and coma.

Investigations show hepatocellular damage, hyperuricaemia, thrombocytopenia, and rarely DIC. CT scanning shows a low density of the liver owing to the high fat content. It can sometimes be difficult to differentiate from the HELLP syndrome and as LCHAD deficiency has also been shown in HELLP there is a view that there is a spectrum of HELLP to AFLP. Liver biopsy shows fine droplets of fat (microvesicular) in hepatocytes with little necrosis, but is not necessary for diagnosis.

Immediate delivery of the child may save both baby and mother. Early diagnosis and treatment has reduced the mortality to less than 20%. Treatment is as for acute liver failure.

LIVER TUMOURS

Secondary liver tumours

The most common liver tumour is a secondary (metastatic) tumour, particularly from the gastrointestinal tract (from the distribution of the portal blood supply), breast or bronchus. They are usually multiple.

Clinical features are variable but usually include weight loss, malaise, upper abdominal pain and hepatomegaly, with or without jaundice.

Diagnosis. Ultrasound is the primary investigation, with CT or MRI to define metastases and look for a primary. The serum alkaline phosphatase is almost invariably raised.

Treatment. This will depend on the site of the primary and the burden of liver metastases. The best results are obtained in colorectal cancer in patients with few hepatic metastases. If the primary tumour is removed and hepatic resection is performed, reasonable survival rates are possible. Chemotherapy is used, particularly with breast cancer (p. 475). Radiofrequency ablation of the metastases is an alternative to surgery. Thermal and cryotherapy is also used.

Primary malignant tumours

Primary liver tumours may be benign or malignant, but the most common are malignant.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide.

Aetiology

Carriers of HBV and HCV have an extremely high risk of developing HCC. In areas where HBV is prevalent, 90% of patients with this cancer are positive for the hepatitis B virus. Cirrhosis is present in approximately 80% of these patients. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see p. 319) and the degree of viral replication (>10000 copies/mL). The risk of HCC in HCV is higher than in HBV (even higher with both HBV and HCV) despite no viral integration. Unlike HBV infection, cirrhosis is always present in HIV. Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis, non-alcoholic fatty liver disease associated cirrhosis, and haemochromatosis. Males are affected more than females. Other aetiological factors are aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic steroids, and there is a weak association with the contraceptive pill.

Pathology

The tumour is either single or occurs as multiple nodules throughout the liver. Histologically it consists of cells resembling hepatocytes. It can metastasize via the hepatic or portal veins to the lymph nodes, bones and lungs.

Clinical features

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly, due to surveillance, HCC is found without symptoms in cirrhotics.

Investigations

Serum α -fetoprotein may be raised, but is normal in at least a third of patients. *Ultrasound* scans show filling defects in 90% of cases. Enhanced CT scans (Fig. 7.28) identify HCC but it is difficult to confirm the diagnosis in lesions <1 cm. An MRI can further help to delineate lesions. Tumour biopsy,

particularly under ultrasonic guidance, is used for diagnosis, but is employed less frequently as imaging techniques show characteristic appearances (hypervascularity of the nodule and lack of portal vein wash out) and because seeding along the biopsy tract can occur.

Treatment and prognosis

See page 478.

Prevention

Persistent HBV infection, usually acquired after perinatal infection, is a high risk factor for HCC in many parts of the world, such as South-east Asia. Widespread vaccination against HBV is being used and this has reduced the annual incidence of HCC in Taiwan.

Cholangiocarcinoma

Cholangiocarcinomas are increasing in incidence and can be extrahepatic (see p. 357) or intrahepatic. Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours. They are not associated with cirrhosis or hepatitis B. In the Far East, they may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini*. The clinical features are similar to primary HCC except that jaundice is frequent with hilar tumours, and cholangitis is more frequent.

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated, outside of specialized protocols.

Benign tumours

The most common benign tumour is a haemangioma. It is usually small and single but can be multiple and large. Haemangiomas are usually found incidentally on ultrasound, CT or MRI and have characteristic appearances. They require no treatment.

Hepatic adenomas are associated with oral contraceptives. They can present with abdominal pain or intraperitoneal bleeding. Resection is only required for symptomatic patients, those with tumours >5 cm diameter or in those in whom discontinuation of oral contraception does not result in shrinkage of the tumour. Immunohistochemical characteristics are helpful in indicating malignant potential, which is far more common in men.

MISCELLANEOUS CONDITIONS OF THE LIVER**Hepatic mitochondrial injury syndromes**

These syndromes – in which there is mitochondrial damage with inhibition of β -oxidation of fatty acids – can be categorized as follows:

- **Genetic**, with abnormalities which include medium-chain acyl-coenzyme A dehydrogenase deficiency leading to microsteatosis.
- **Toxins** leading to liver failure include aflatoxin and cerulide (produced by *Bacillus cereus*) which causes food poisoning (see p. 343).
- **Drugs** (e.g. i.v. tetracycline, valproic acid and nucleoside reverse-transcriptase inhibitors) can produce a fatal microsteatosis.
- **Idiopathic**, the best known being fatty liver of pregnancy (p. 346) and Reye's syndrome. The latter,

due to inhibition of β -oxidation and uncoupling of oxidative phosphorylation in mitochondria, leads in children to an acute encephalopathy and diffuse microvesicular fatty infiltration of the liver. Aspirin ingestion and viral infections have been implicated as precipitating agents. Mortality is about 50%, usually due to cerebral oedema.

Idiopathic adult ductopenia

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tracts, together with the features of cholestasis and marked fibrosis or cirrhosis. In most, the disease is progressive and the only treatment is liver transplantation.

Indian childhood cirrhosis

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually, there is development of a micronodular cirrhosis with excess copper in the liver.

Hepatic porphyrias

These are dealt with on page 1043.

Cystic fibrosis (see also p. 821)

This disease affects mainly the lung and pancreas, but patients can develop fatty liver, cholestasis and cirrhosis. The aetiology of the liver involvement is unclear.

Coeliac disease (see also p. 285)

Abnormal liver biochemical tests are common and return to normal with a gluten-free diet. A tissue transglutaminase should be performed when hepatic causes are not found when investigating abnormal liver biochemistry.

DRUGS AND THE LIVER**Drug metabolism**

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (p. 901).

Drug hepatotoxicity

Many drugs impair liver function. When abnormal liver biochemical tests are found, drugs should always be considered as a cause, particularly when other causes have been excluded. Damage to the liver by drugs is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see p. 904). However, there is considerable overlap and at least six mechanisms may be involved in the production of damage:

1. Disruption of intracellular calcium homeostasis
2. Disruption of bile canalicular transport mechanisms
3. Formation of non-functioning adducts (enzyme-drug), which may then
4. Present on the surface of the hepatocyte as new immunogens (attacked by T cells)
5. Induction of apoptosis

6. Inhibition of mitochondrial function, which prevents fatty acid metabolism and accumulation of both lactate and reactive oxygen species.

The predominant mechanism or combination of mechanisms determines the type of liver injury, i.e. hepatitic, cholestatic or immunological (skin rashes, fever and arthralgia, i.e. serum-sickness syndrome). Eosinophilia and circulating immune complexes and antibodies are occasionally detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g. paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, while the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (p. 918).

The 'predictability' of drugs to produce damage can, however, be affected by metabolic events preceding their

ingestion. For example, chronic alcohol users may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors such as environmental or genetic effects may be involved in determining the 'susceptibility' of certain patients to certain drugs.

The incidence of drug hepatotoxicity is 14 per 100 000 population with a 6% mortality. It is the most common cause of acute liver failure in the USA. Liver transplantation is used.

Hepatitic damage

The type of damage produced by various drugs is shown in Table 7.16. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as antituberculosis therapy, is **mandatory**. If a drug is suspected of causing hepatic damage it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally hepatic

eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

Individual drugs

Paracetamol. In high doses paracetamol produces liver cell necrosis (see above). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed on page 918.

Halothane and other volatile liquid anaesthetics. Halothane, which is available in the UK on a named patient basis, produces hepatitis in patients having repeated exposures. The mechanism is thought to be a hypersensitivity reaction. An unexplained fever occurs approximately 10 days after the second or subsequent halothane anaesthetic and is followed by jaundice, typically with a hepatitic picture. Most patients recover spontaneously but there is a high mortality in severe cases. There are no chronic sequelae. Both sevoflurane and isoflurane also cause hepatotoxicity in those sensitized to halogenated anaesthetics but the risk is smaller than with halothane and remote with desflurane.

Steroid compounds. Cholestasis is caused by natural and synthetic oestrogens as well as methyltestosterone. These agents interfere with canalicular biliary flow by blocking MRP2 and MDR3 (see Fig. 7.4) and cause a pure cholestasis. Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas (rarely HCCs), the Budd–Chiari syndrome and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilatation of the hepatic sinusoids to form blood-filled lakes.

Phenothiazines. Phenothiazines (e.g. chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity

reaction. It occurs in 1% of patients, usually within 4 weeks of starting the drug. Typically, it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

Antituberculous chemotherapy. Isoniazid produces elevated aminotransferases in 10–20% of patients. Hepatic necrosis with jaundice occurs in a smaller percentage. The hepatotoxicity of isoniazid is related to its metabolites and is dependent on acetylator status. *Rifampicin* produces hepatitis, usually within 3 weeks of starting the drug, particularly in patients on high doses. *Pyrazinamide* produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

Amiodarone. This leads to a steatohepatitis histologically and liver failure if the drug is not stopped in time.

Sodium valproate. This causes mitochondrial injury with microvesicular steatosis. Intravenous carnitine should be used as an antidote.

Drug prescribing for patients with liver disease

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites) as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoproteinaemia there is decreased protein binding of some drugs, and bilirubin competes with many drugs for the binding sites on serum albumin. In patients with portosystemic encephalopathy, care must be taken in prescribing drugs with a central depressant action, e.g. narcotics, including codeine and anxiolytics. Other common drugs to be avoided in cirrhosis include ACE inhibitors (cause hepatorenal failure) and NSAIDs (bleeding).

GALL BLADDER AND BILIARY SYSTEM

The structure, formation and function of bile is discussed on page 305.

GALLSTONES

Prevalence of gallstones

Gallstones may be present at any age but are unusual before the 3rd decade. The prevalence of gallstones is strongly influenced both by age and gender. There is a progressive increase in the presence of gallstones with age but the prevalence is two to three times higher in women than in men, although this difference is less marked in the 6th and 7th decade. At this age, the prevalence ranges between 25% and 30%. The increase in life expectancy is reflected in an increased burden of symptomatic gallstone disease. There are considerable racial differences, gallstones being more common in Scandinavia, South America and Native North Americans but less common in Asian and African groups.

Types of gallstones

The large majority of gallstones are of two types: cholesterol (containing >50% of the sterol) and less frequently 'pigment

stones', being predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper and some cholesterol.

Cholesterol gallstones

This type of stone accounts for 80% of gallstones in the western world. The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent upon three factors:

- Cholesterol supersaturation of bile
- Crystallization-promoting factors within bile
- Motility of the gall bladder.

The majority of cholesterol is derived from hepatic uptake from dietary sources. However, hepatic biosynthesis may account for up to 20%. The rate-limiting step in cholesterol synthesis is β -hydroxy- β methyl glutaryl CoA (HMG-CoA) reductase, which catalyses the first step, i.e. the conversion of acetate to mevalonate. The cholesterol formed is co-secreted with phospholipids into the biliary canaliculus as unilamellar vesicles. Cholesterol will only crystallize into stones when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity. Recently, leptin

(see p. 216) has been shown to increase cholesterol secretion into bile. Elevated levels of leptin during rapid weight loss may account for the increased incidence of cholesterol gallstones. An alternative mechanism of supersaturation is a decreased *bile salt content* which may occur as a consequence of bile salt loss (e.g. terminal ileal resection or ileal involvement with Crohn's disease).

The *composition* of the bile salt pool may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of the secondary hydrophobic bile acid (deoxycholic acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit during which the primary bile acid cholic acid may undergo microbial enzyme metabolism yielding deoxycholic acid which is then absorbed back into the bile salt pool (see Fig. 7.4).

While cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determines whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

There is increasing evidence from epidemiological, family and twin studies of the role of genetic factors in gallstone formation. A number of lithogenic genes have been identified which may interact with environmental factors. The process of bile formation is maintained by a network of ATP-binding cassette (ABC) transporters in the hepatocyte canalicular membrane which enable biliary secretion of cholesterol, bile salts and phospholipids. This process is regulated by the nuclear receptors FXR and LXR. Loss of function mutations in specific ABC transporter genes have been associated with cholesterol gallstones secondary to bile salt and phospholipid deficiencies within the nascent bile (Fig. 7.29). However, monogenic susceptibility appears uncommon. There are rare cases in which a single missense mutation of the MDR3 gene has been associated with extensive intra- and extrahepatic cholelithiasis at an early (<40 years) age.

A high cholesterol diet increases biliary cholesterol secretion and decreases bile salt synthesis and bile salt pool in cholesterol gallstone subjects but not in controls. These findings suggest that increased intestinal uptake of the sterol could play a role in gallstone pathogenesis. In support of this observation, pharmacological inhibition of cholesterol absorption prevents gallstone formation in a mouse model. This may offer a potential therapy for the management/prevention of gallstone formation in patients.

Gall bladder motility represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin.

Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity and diabetes as well as octreotide-related gall bladder stones (p. 954). Recognized risk factors for gallstones are shown in Table 7.17.

Bile pigment stones

The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstones, black and brown.

Black pigment gallstones are composed of calcium bilirubinate and a network of mucin glycoproteins that interlace with salts such as calcium carbonate and/or calcium phosphate. These stones range in colour from deep black to

Figure 7.29 Nascent bile formation at the hepatocytic canalicular membrane, biliary cholesterol solubilization and gallstone formation. ABCG5-G8 transports cholesterol into bile (regulated by nuclear receptor LXR). ABCB11, ABCB4 transport bile salts and phosphatidylcholine into bile (regulated by nuclear receptor FXR). Bile cholesterol is solubilized in mixed micelles or contained in cholesterol-phospholipid vesicles. Most gallstones are due to excess biliary cholesterol secretion and subsequent crystallization from supersaturated vesicles (continuous lines). LPAC (low phospholipid associated cholelithiasis) occurs if there is phospholipid in bile due to function mutations in gene *ABCB4*. Benign recurrent intrahepatic cholestasis (BRIC) type 2 is characterized by bile salts in bile due to function mutations in gene *ABCB11*. In both LPAC and BRIC type 2, there is increased risk of gallstone formation.

Table 7.17 Risk factors for cholesterol gallstones

Increasing age
Sex (F > M)
Family history
Multiparity
Obesity ± metabolic syndrome
Rapid weight loss
Diet (e.g. high in animal fat/low in fibre)
Drugs (e.g. contraceptive pill)
Ileal disease or resection
Diabetes mellitus
Acromegaly treated with octreotide
Liver cirrhosis

very dark brown and have a glass-like cross-sectional surface on fracturing. Black pigment stones are seen in 40–60% of patients with haemolytic conditions such as sickle cell disease and hereditary spherocytosis in which there is chronic excess bilirubin production. However, the majority of pigment stones occur without haemolysis. There has been evidence that bile salt loss into the colon (consequent upon ileal resection or ileal disease) promotes solubilization and colonic reabsorption of bilirubin. This enhances the enterohepatic circulation and biliary secretion of bilirubin with

FURTHER READING

Wang HH, Portincasa P, Mendez-Sanchez, N et al. Effect of ezetimibe on the prevention and dissolution of cholesterol gallstones. *Gastroenterology* 2008; 134: 2101–2110.

the formation of gallstones. Pigment stones have also been linked with bacterial colonization of the biliary tree. Some pigment stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for the pigment stone formation.

Brown stones are usually of a muddy hue and on cross-section seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones are a common cause of recurrent bile duct stones following cholecystectomy and may also be found in the intrahepatic ducts in circumstances of duct disease such as Caroli's syndrome and primary sclerosing cholangitis. In the Far East such brown stones are identified within both the intra- and extrahepatic biliary tree and have been linked with chronic parasitic infection.

Clinical presentation of gallstones

The majority of gallstones are asymptomatic and remain so during a person's lifetime. Gallstones (Fig. 7.30) are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning. Over a 10–15-year period, approximately 20% of these stones will be the cause of symptoms with 10% having severe complications. Once gallstones have become symptomatic there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, flatulence or other vague upper abdominal symptoms.

Biliary or gallstone colic

Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or common bile duct by a stone usually migrating from the gall bladder. Despite the term 'colic', the pain of stone-induced ductular obstruction is severe but constant and has a crescendo characteristic. Many sufferers can relate the symptoms to over-indulgence with food, particularly when this has a high fat content. The most common time of day for such an episode is in the mid-evening and lasting until the early hours of the morning.

The initial site of pain is usually in the epigastrium but there may be a right upper quadrant component. Radiation may occur over the right shoulder and right subscapular region.

Nausea and vomiting frequently accompany the more severe attacks. The cessation of the attack may be

spontaneous after a number of hours or terminated by the administration of opiate analgesia. More protracted pain, particularly when associated with fevers and rigors, suggests secondary complications such as cholecystitis, cholangitis or gallstone-related pancreatitis (see below).

Acute cholecystitis

The initial event in acute cholecystitis is obstruction to gall bladder emptying. In 95% of cases, a gall bladder stone can be identified as the cause. Such obstruction results in an increase of gall bladder glandular secretion leading to progressive distension which in turn may compromise the vascular supply to the gall bladder.

There is also an inflammatory response secondary to retained bile within the gall bladder. Infection is a secondary phenomenon following the vascular and inflammatory events described above.

The initial clinical features of an episode of cholecystitis are similar to those of biliary colic described above. However, over a number of hours, there is progression with severe localized right upper quadrant abdominal pain corresponding to parietal peritoneal involvement in the inflammatory process. The pain is associated with tenderness and muscle guarding or rigidity. Occasionally the gall bladder can become distended by pus (an empyema) and rarely an acute gangrenous cholecystitis develops which can perforate, with generalized peritonitis.

Investigations

Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. Acute cholecystitis is usually associated with a moderate leucocytosis and raised inflammatory markers (e.g. C-reactive protein).

- **The serum bilirubin, alkaline phosphatase and aminotransferase levels** may be marginally elevated in the presence of cholecystitis alone, even in the absence of bile duct obstruction. More significant elevation of the bilirubin and alkaline phosphatase is in keeping with bile duct obstruction.
- **An abdominal ultrasound scan** is the single most useful investigation for the diagnosis of gallstone-related disease (Fig. 7.31). It has a positive predictive value of

Figure 7.30 Clinical presentation of gallstones.

Figure 7.31 Ultrasound scan in a patient with acute cholecystitis. There is a stone (casting an acoustic shadow – thin arrow) impacted in the gall bladder neck, with a distended gall bladder (thick arrow) and thickening and oedema of the gall bladder wall.

92% and a negative predictive value of 95% in patients with a clinical history of acute cholecystitis and Murphy's sign. Look for:

- *Gallstones* within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct
- *Focal tenderness* over the underlying gall bladder
- *Thickening of the gall bladder wall*. This may also be seen with hypoalbuminaemia, portal hypertension and acute viral hepatitis.

Gallstones are a common finding in an ageing population, and in the absence of specific symptoms great care should be taken when determining whether the gallstones are responsible for the symptoms.

- **Biliary scintigraphy using technetium derivatives of iminodiacetate**. These isotopes are taken up by hepatocytes and excreted into bile. They delineate the extrahepatic biliary tree. The absence of cystic duct and gall bladder filling provides evidence towards acute cholecystitis although the findings must be closely correlated with the presenting symptoms.

Differential diagnosis

Typical cases of biliary colic are usually suspected by the clinical history. The differential diagnosis includes the irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain and fever, e.g. acute episodes of pancreatitis, perforated peptic ulceration or an intrahepatic abscess. Conditions above the right diaphragm such as basal pneumonia as well as myocardial infarction may on occasions mimic the clinical picture.

Management of gall bladder stones

Cholecystectomy

Cholecystectomy is the treatment of choice for virtually all patients with *symptomatic* gall bladder stones. In patients admitted with specific gallstone-related complications (see below), cholecystectomy should be carried out during the period of that admission to prevent the risk of recurrence. For those presenting with pain alone an elective procedure can be planned but the waiting time should be minimized to avoid the high risk of recurrent symptoms (approximately 30% over 4 months) and the need for another hospital admission.

Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. There is an ongoing debate as to whether prophylactic cholecystectomy is justified in young patients found to have small stones. Such patients have a long period over which they may develop symptomatic disease and small stones are an independent risk factor for the potentially serious complication of gallstone pancreatitis. Each case should be discussed on an individual risk benefit basis.

The laparotomy approach to cholecystectomy has now been replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy can be safely carried out on a day-care basis in otherwise fit patients (although in most cases an overnight

stay remains the norm). This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications such as extensive previous upper abdominal surgery, ongoing bile duct obstruction or portal hypertension.

In approximately 5% of cases a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties, in particular adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

Acute cholecystitis

The initial management is conservative, consisting of nil by mouth, intravenous fluids, opiate analgesia and intravenous antibiotics (dictated by local policy with options including extended-spectrum cephalosporins, fluoroquinolones or piperacillin/tazobactam).

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. In this circumstance urgent imaging (trans-abdominal ultrasound or CT scan) is required to define the pathology. Surgical intervention is usually required although a radiologically placed gall bladder drain can be used as a *temporizing measure for the management of an empyema*.

Specific complications of cholecystectomy include a biliary leak either from the cystic duct or from the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of a bile duct stricture and secondary biliary liver injury. There is an overall mortality of 0.2%.

Stone dissolution and shock wave lithotripsy

These non-surgical techniques for the management of gall bladder stones are infrequently used but still have a role in a few highly selected patients who may not be fit for cholecystectomy or have declined the surgical option.

Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Oral chenodeoxycholic acid and ursodeoxycholic acid have been successfully utilized. The approach requires long-term therapy and the recurrence rate of gallstones is high when therapy is stopped. Additional pharmacological tools for treating cholesterol gallstones include cholesterol-lowering agents that inhibit hepatic cholesterol synthesis (statins) or intestinal cholesterol absorption (ezetimibe), or drugs acting on specific nuclear receptors involved in cholesterol and bile acid homeostasis.

Extracorporeal shock wave lithotripsy

A shock wave can be directed either radiologically or by ultrasound on to gall bladder stones. This technique was highly successful but in only a restricted patient population.

The post-cholecystectomy syndrome

This refers to right upper quadrant pain, often biliary in type, which occurs a few months after the cholecystectomy but may be delayed for a number of years. The patients often comment that the pain is identical to that for which the original operation was carried out. In many cases this syndrome is related to functional large bowel disease with colonic spasm at the hepatic flexure (hepatic flexure syndrome). In a small proportion of patients the pain is a result of a retained common bile duct stone. In a further minority of patients, hypertension of the sphincter of Oddi is a potential cause.

This is most likely in patients with abnormal liver biochemistry and dilatation of the common bile duct (on ultrasound) during episodes of pain (and in the absence of a documented retained stone). The diagnosis is confirmed by pressure measurements of the sphincter of Oddi, and the condition can be successfully managed by endoscopic sphincterotomy (see below).

Common bile duct stones

The classical features of common bile duct (CBD) stones are biliary colic, fever and jaundice (acute cholangitis). This triad is only present in the minority of patients. Abdominal pain is the most common symptom and has the typical features of biliary colic (see above). Jaundice is a variable accompaniment and is almost always preceded by abdominal pain. A patient with bile duct stones may experience sequential episodes of pain, only some of which are accompanied by jaundice. In contrast to malignant bile duct obstruction, the level of jaundice associated with CBD stones characteristically tends to fluctuate. In the elderly or immunocompromised patient cholangitis may present with very nonspecific symptoms and only associated abnormal liver biochemistry may point to the diagnosis.

Fever is only present in a minority of cases but indicates biliary sepsis and sometimes an associated septicaemia. The presence of such biliary sepsis is a significant adverse prognostic factor.

A minority of patients with bile duct stones are discovered incidentally during imaging for gall bladder disease. A total of 15% of patients undergoing cholecystectomy will have stones within the bile duct only detected at the time of operative cholangiography. The frequency of asymptomatic bile duct stones resulting in complications is not well documented. It is likely that many such stones will pass into the duodenum without causing symptoms. However, the potential for serious complication is well recognized and in most circumstances incidentally identified bile duct stones are removed (see below).

Physical examination

If the patient is examined between episodes, there may be no abnormal physical finding. During a symptomatic episode the patient may be jaundiced with a fever and associated tachycardia. There is tenderness in the right upper quadrant varying from mild to extremely severe.

More widespread abdominal tenderness extending from the epigastrium to the left upper quadrant, associated with distension, may indicate associated stone-related pancreatitis (see below).

Investigations

Laboratory tests

- **Full blood count** is usually normal in the presence of uncomplicated bile duct stones.
- **An elevated neutrophil count** and raised inflammatory markers (ESR and CRP) are frequent accompaniments of cholangitis.
- **The raised serum bilirubin** tends to be mild and often transient. Very high concentrations of bilirubin ($>200 \mu\text{mol/L}$) almost always reflect complete bile duct obstruction.
- **Serum alkaline phosphatase and γ -glutamyl transpeptidase** are similarly elevated in proportion to the degree of hyperbilirubinaemia.

- **Aminotransferase levels** are usually mildly elevated but with complete bile duct obstruction there may be very marked rises to 10–15 times the normal value. The alanine aminotransferase is characteristically higher than the aspartate aminotransferase. These high levels may lead to an initial misdiagnosis of a hepatic process.
- Serum amylase levels are often mildly elevated in the presence of bile duct obstruction but are markedly so if stone-related pancreatitis has occurred.
- Prothrombin time may be prolonged if bile duct obstruction has occurred; this reflects decreased absorption of vitamin K.

Imaging

Transabdominal ultrasound is the initial imaging technique of choice.

Bile duct obstruction is characterized by dilatation of intrahepatic biliary radicles, which are usually easily detected by the ultrasound scan. It may, however, not be possible to identify the cause of obstruction. Stones situated in the distal common bile duct are poorly visualized by transabdominal ultrasound and up to 50% are missed. The detection of stones within the gall bladder is poorly predictive as to the cause of bile duct obstruction. Asymptomatic gallstones are common (up to 15%) in patients who are 65 years and older. Conversely, in 5–10% of patients with bile duct stones, no calculi can be seen within the gall bladder.

Magnetic resonance cholangiography (MRC) delineates the fluid column within the biliary tree and is a sensitive technique for the detection of common bile duct stones in the presence of a dilated duct. The technique may be less accurate in the absence of duct dilatation (see the role of endoscopic ultrasound, below) (Fig. 7.32).

CT scanning is an alternative way to detect bile duct dilatation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning also provides a means of excluding other causes of bile duct obstruction such as carcinoma of the head of the pancreas.

Endoscopic ultrasound scanning (Figs 7.33, 7.34) has enabled high-resolution imaging of the common bile duct, gall bladder and pancreas, although unlike the preceding imaging techniques it is an invasive procedure. The endoscopic ultrasound probe in the duodenum is in close proximity with the distal common bile duct and hence can identify the majority of stones at this level.

This technique is particularly useful for identifying small calculi (microcalculi), in a non-dilated common bile duct.

Endoscopic retrograde cholangiography (ERC)

In experienced hands, visualization of the common bile duct will be successful in 98% of cases, providing good documentation of bile duct stones (Fig. 7.32, Fig. 7.35). However, microcalculi can still be missed. ERC is an invasive procedure with recognized risks. In almost all circumstances this is a therapeutic tool used to remove the stones that have been identified by the investigations described above.

Differential diagnosis

Cholangitis may occur independently of gallstones in any condition associated with impaired biliary drainage. It is commonly associated with conditions such as primary sclerosing cholangitis and Caroli's syndrome. Cholangitis may also complicate post-traumatic or surgery-associated bile duct strictures. It is unusual in malignant bile duct obstruction

a

Figure 7.32 (a) A magnetic resonance cholangiogram in a patient presenting with abdominal pain and jaundice. This shows evidence of a distal common bile duct stricture with a stone in the bile duct proximal (arrows). (b) An ERCP in the same patient confirming the details identified in the MRCP scan. The stones (arrowed) were removed at the time of the ERCP after initial dilatation of the stricture.

Figure 7.33 An endoscopic ultrasound scan with the probe in the first part of the duodenum identifying the gall bladder (GB) and multiple small echo-poor stones within (microlithiasis). The patient had presented with recurrent episodes of unexplained abdominal pain.

Figure 7.34 An endoscopic ultrasound scan with the probe within the first part of the duodenum (D1) and defining the common bile duct (BD) and a stone (S) clearly identified within the lumen of the common bile duct.

Figure 7.35 An ERCP carried out in a patient with abdominal pain, fluctuating jaundice and fever. The cholangiogram shows a markedly dilated biliary tree (arrowed) with multiple large stones within (ST). These stones were removed at the time of ERCP using a mechanical lithotripsy device to crush the stones before removing from the duct by means of balloon and basket retrieval.

unless there has been prior endoscopic or surgical intervention. Jaundice may also be a feature of acute cholecystitis in the absence of bile duct stones. A stone impacted in the cystic duct may compress and obstruct the bile duct (Mirizzi's syndrome). Common bile duct stones may produce pain, but in the absence of jaundice, the differential diagnosis is that of biliary colic (see above).

Management

Acute cholangitis has a high morbidity and mortality, particularly in the elderly. Successful management depends on intravenous antibiotics (see as for acute cholecystitis), and urgent bile duct drainage. In most circumstances this is achieved by the endoscopic retrograde approach. Access to the bile duct is achieved by sphincterotomy, and thereafter the stones can be removed either by balloon or basket catheters. In the severely ill patient a piece of plastic tubing (termed a stent) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones; hence minimizing the time period to complete the procedure. The residual stones can then be removed endoscopically when the patient has recovered from the episode. If endoscopic drainage is not available or prevented by inability to access the second part of the duodenum then a radiologically placed percutaneous biliary drain represents an alternative management option. Surgical drainage has been associated with a high mortality and is now limited to those very few cases which cannot be managed by the endoscopic or percutaneous approach.

Urgent endoscopic bile duct clearance is also indicated in some patients with acute gallstone pancreatitis (see below). Patients who have retained common bile duct stones after a previous cholecystectomy are also optimally managed by endoscopic clearance. Patients shown to have common bile duct stones as well as gall bladder stones may be treated by two different approaches:

- **Laparoscopic cholecystectomy** which can also include exploration of the CBD via the cystic duct or by direct choledochotomy. By using these techniques the laparoscopist can extract stones from the CBD. This, however, prolongs the procedure, particularly in the presence of large stones or biliary sepsis.
- **Endoscopic approach** either immediately before or after the cholecystectomy. Removal of CBD stones by this method is the preferred way in the UK. Large bile duct stones (>10 mm) may present a significant challenge to endoscopic removal. Mechanical lithotripsy facilitates stone fragmentation and removal into the duodenum. Both extracorporeal and intraductal shock wave stone fragmentation has also been used.

Complications of gallstones

- Acute cholecystitis and acute cholangitis have been discussed (p. 353).
- Gallstone-related pancreatitis is discussed on page 363.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine giving rise to a biliary enteric fistula. Passage of a gallstone through into the small bowel can give rise to an ileus or true obstruction.
- There is little evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (p. 357).

MISCELLANEOUS CONDITIONS OF THE BILIARY TRACT

Gall bladder

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms.

Non-calculous cholecystitis

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as non-calculous cholecystitis. In many instances the gall bladder inflammation is minor and of doubtful significance. In a minority of cases non-calculous cholecystitis is characterized by severe inflammation frequently associated with gall bladder perforation. This condition is characteristically found in an elderly and critically ill group of patients. Chemical inflammation of the gall bladder may also occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater. Bacterial and viral infections of the gall bladder have been recognized as a cause of non-calculous cholecystitis.

The decision to carry out cholecystectomy in the absence of defined gall bladder stones should be guided by the specific features of the history and whether there is evidence of a diseased gall bladder wall on ultrasound scanning.

Cholesterosis of the gall bladder

In cholesterosis, cholesterol and other lipids are deposited in macrophages within the lamina propria of the gall bladder. These may be diffusely situated, giving a granular appearance to the gall bladder wall, or on occasions more discrete, giving a polypoid appearance (see below). Cholesterosis of the gall bladder may co-exist with gallstones but occurs independently. Some degree of cholesterosis may be found in up to 25% of autopsies in an elderly population. It is doubtful whether this is a cause of symptoms.

Adenomyomatosis of the gall bladder

Adenomyomatosis is a gall bladder abnormality characterized by hyperplasia of the mucosa, thickening of the muscle wall and multiple intramural diverticula (the so-called 'Rokitansky-Aschoff sinuses').

The condition is usually detected as an incidental finding during investigation for possible gall bladder disease. It has been suggested that this condition is secondary to increased intraluminal gall bladder pressure but this is not proven. Gallstones may frequently co-exist but there is no evidence to support a direct relationship.

It is unlikely that adenomyomatosis alone is a cause of biliary symptoms.

Chronic cholecystitis

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation, and occasionally a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people

and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain suffer from functional bowel disease (p. 230).

Extrahepatic biliary tract

Primary sclerosing cholangitis (see p. 334)

In up to 40% of patients with PSC the clinical course is influenced by a dominant extrahepatic/hilar stricture. This is relevant in those patients who do not have established advanced liver involvement in whom maintaining bile flow can protect the liver from secondary biliary injury. Drainage with a surgical hepaticojejunostomy has been beneficial in some cases. More recently repeated endoscopic balloon dilatation and temporary stenting of the extrahepatic/hilar stricture has been reported with prolonged benefit.

Autoimmune cholangitis

Immunoglobulin (Ig)G4-associated cholangitis is the biliary manifestation of a multisystem fibroinflammatory disorder in which affected organs have a characteristic lymphoplasmacytic infiltrate rich in IgG4-positive cells. The original description of this condition was in the context of autoimmune pancreatitis (see p. 365). The large majority of cases are recognized in middle-aged or elderly men and presentation is varied depending upon the systems involved but includes abdominal pain and jaundice. Both intra- and extrahepatic biliary strictures may be seen and the findings may be misinterpreted as representing cholangiocarcinoma. The diagnosis relies upon clinical suspicion and confirmation of an elevated serum IgG4 level and a typical lymphocytotoxic infiltrate on histological examination of involved tissue. The condition is almost always responsive to steroids but can lead to hepatic failure.

Choledochal malformation (cysts)

Congenital malformation of the bile ducts may occur at all levels of the biliary tree, although most commonly are extrahepatic. The resulting dilatation of the choledochus may be saccular, diverticular or of fusiform configuration. In many cases there is associated pancreatobiliary malunion with the pancreatic duct draining directly into the common bile duct. The majority of symptomatic cases present in childhood with features of cholangitis. The formation of stones and sludge within the cystic segment may predispose to acute relapsing pancreatitis. In adult life, choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. The cyst must be fully resected to avoid the recurrent biliary complications as well as averting the risk (approximately 15%) of subsequent cholangiocarcinoma.

Benign bile duct strictures

Benign strictures are a recognized complication of biliary surgery. This may include inadvertent stapling of the duct or as a consequence of ischaemic injury (often in association with a bile duct leak). A stricture may also occur at the level of a bile duct anastomosis either enteric or duct to duct. A bile duct stricture can also result from major trauma to the right upper quadrant. The distal common bile duct is commonly compressed in the presence of chronic pancreatitis (see below).

In most cases the initial therapy will be endoscopic including balloon dilatation of the stricture and temporary

bile duct stenting (see below). This may provide definitive management but in some cases surgical intervention is required.

Haemobilia

Haemobilia is the term used to describe bleeding into the biliary tree. This may be as a consequence of liver trauma or as a complication of liver surgery. Biopsy of the liver is also a well-recognized cause. The end result is a fistula between a branch of the hepatic artery and an intrahepatic bile duct.

Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is suspected, bleeding may be managed by occlusion of the feeding artery by thrombosis performed radiologically.

Some patients will require surgery to control the bleeding point.

TUMOURS OF THE BILIARY TRACT

Gall bladder polyps

Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary ultrasonography. The vast majority of these are small (<5 mm), are non-neoplastic and are inflammatory in origin or composed of cholesterol deposits (see above). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have a cancerous potential. The only reliable means of defining those at risk is polyp size (>10 mm). Cholecystectomy is recommended for any polyp approximating to 1 cm in diameter or larger.

Primary cancer of the gall bladder

Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is in the early 60s, with a women to men ratio of 3:1. Gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 10 mm in diameter are also recognized as premalignant lesions (see above).

Carcinoma of the gall bladder is often detected at the time of planned cholecystectomy for gallstones and in such circumstances resection of an early lesion may be curative. Early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. There are no proven chemotherapeutic agents for carcinoma of the gall bladder. A small proportion of cases are sensitive to radiotherapy but the overall 5-year survival is less than 5%.

Cholangiocarcinoma (see also p. 348)

Cancer of the biliary tree may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A

number of associations have been identified such as that with choledochal malformation (see above), and with primary sclerosing cholangitis. Chronic infection of the biliary tree with, e.g. *Clonorchis sinensis*, has also been implicated. The bile duct malignancy usually presents with jaundice and may be suspected by imaging, initially ultrasound and thereafter CT and in particular magnetic resonance cholangiopancreatography (MRCP). Histological/cytological diagnosis may be difficult to attain because the malignant cells are often few in number and contained within a dense stroma. Endoscopically obtained cytology specimens have only 30% sensitivity. This can be enhanced by using techniques such as fluorescent in situ hybridization and digital image analysis. Improved techniques of endoscopic cholangioscopy have enabled direct visualization of the lesions and allowing targeted biopsy.

The disease spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach including partial hepatic resection. Chemoradiation has been used to treat localized small hilar cholangiocarcinoma and in a few cases has facilitated successful liver transplantation, but the carcinoma recurs.

Secondary malignant involvement of the biliary tree

Carcinoma of the head of the pancreas frequently presents with common bile duct obstruction and jaundice. Metastases to the bile ducts from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so.

Other carcinomas that have caused bile duct metastases, in order of frequency, are those arising in the lung, breast and colon as well as those from the pancreas (metastatic as compared to direct infiltration). Infiltration of the bile duct is not uncommon in disseminated lymphomatous disease.

Palliation of malignant bile duct obstruction

A small proportion of cholangiocarcinomas are surgically resectable, more commonly those in the distal bile duct as compared to the hilar region. All patients must be fully screened for operability using the imaging techniques described above. However, in the greater proportion of patients the treatment is palliative. Relief of bile duct obstruction has been shown to improve quality of life considerably and with pain control is the major end point of palliation. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents which have considerably longer periods of patency (Fig. 7.36). In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative method of stent placement. There is some evidence of benefit from the use of photodynamic therapy in those patients in whom biliary drainage has been achieved. This technique involves the use of a porphyrin derivative to sensitize the malignant cells prior to activation by an endoscopically placed laser probe. The aim is to provide local tumour destruction and maintain bile duct patency.

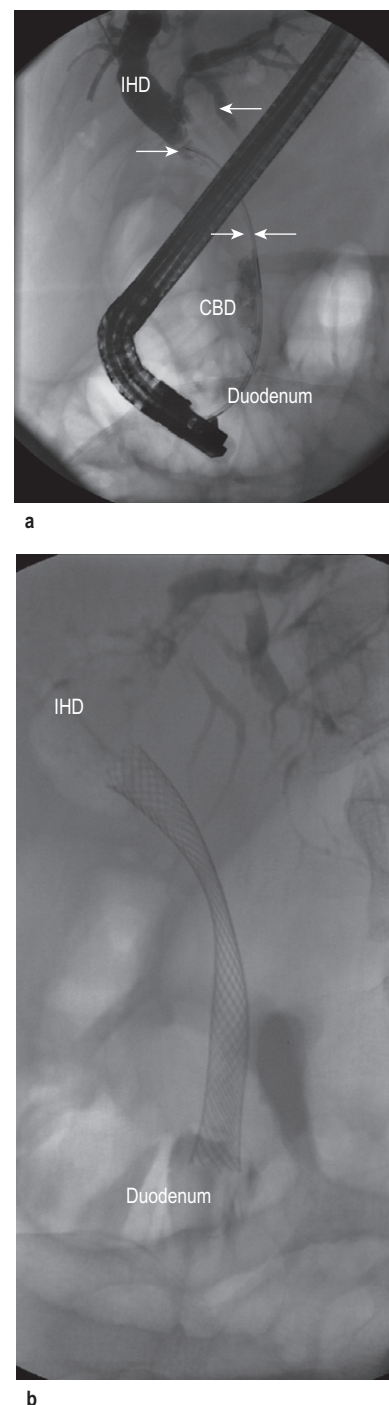

Figure 7.36 An ERCP in a patient presenting with painless jaundice. (a) There is a tight stricture in the mid-common bile duct (CBD) and extending proximally over 4 cm (extent defined by arrows). The intrahepatic ducts (IHD) proximally are dilated. A catheter has been placed endoscopically across the stricture. (b) A self-expanding metal stent has been placed across the stricture and released. The stent is compressed at the level of the stricture but will open fully over 24 h. The contrast in the intrahepatic ducts (IHD) has largely drained through the stent. The distal margin of the stent is in the duodenum.

THE PANCREAS

STRUCTURE AND FUNCTION

Structure

The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. The head is encircled by the duodenum; the body, which forms the main bulk of the organ, ends in a tail that lies in contact with the spleen. The pancreas consists of exocrine and endocrine cells, the former making up 98% of the human pancreas.

The pancreatic acinar cells are grouped into lobules, forming the ductal system which eventually joins into the main pancreatic duct.

The main pancreatic duct has many tributary ductules and gradually tapers towards the tail of the pancreas. The main pancreatic duct itself usually joins the common bile duct to enter the duodenum as a short single duct at the ampulla of Vater.

Exocrine function

The pancreatic acinar cells are responsible for production of digestive enzymes. These include amylase, lipase, colipase, phospholipase and the proteases (trypsinogen and chymotrypsinogen). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 7.37).

After ingestion of a meal, pancreatic exocrine secretion is regulated by cephalic, gastric and intestinal stimuli. The cephalic phase is mediated by the central nervous system and is stimulated by behavioural cues related to the sight and smell of food. With ingestion of food, the gastric phase commences and in response to distension of the stomach a neural pathway involving the central nervous system stimulates pancreatic secretion. Both these phases are under vagal control. Finally, the presence of protein, fat and gastric acid within the small intestine further augments pancreatic secretion by both hormonal and neurotransmitter activity which produces local enteropancreatic control of secretion. Feedback regulatory events eventually terminate pancreatic secretion.

Cholecystokinin (CCK) is produced in specialized gut endocrine cells (I cells) of the mucosa of the small intestine and is secreted in response to intraluminal food. In animals, it exerts its biological activity by binding to specific G-protein-coupled receptors on target cells in the pancreas. Activated G-proteins lead to the activation of phospholipases. This in turn leads to calcium release from intracellular stores, which in turn results in the fusion of the digestive enzyme granules to the apical plasma membrane and enzyme release. There are no CCK receptors in pancreatic cells in humans, and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion. Of the enzymes produced by the pancreatic acinar cells, the proteases and colipase are secreted as inactive precursors and require duodenal enterokinase to initiate activity.

Secretin is also released from specialized enteroendocrine cells of the small intestine during a meal and in particular during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action

Figure 7.37 Stimulus-secretion coupling of pancreatic cell protein secretion. There is no CCK receptor in humans; stimulation is probably via neural fibres. VIP, vasoactive intestinal polypeptide; CCK, cholecystokinin; ACh, acetylcholine.

is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

Completion of the postprandial secretory phase involves both neural and hormonal control.

Central neuronal inhibition of pancreatic secretion acts through dopamine and somatostatin receptors mediated by noradrenergic nerves.

Pancreatic polypeptide from the islet cells is released from the pancreas in response to a meal and has an inhibitory effect upon acinar enzyme secretion both by a local effect and via central receptors.

Somatostatin, present within the pancreas, stomach and central nervous system, is released in response to food. Its effect is mediated both by direct pancreatic acinar inhibition and by a central nervous system effect.

Two other mechanisms of inhibition have been described. First, *proteases* within the duodenal lumen have a negative feedback on acinar secretion. Second, nutrients within the ileum inhibit pancreatic secretion by means of local hormone release (peptide YY and glucagon-like peptide) acting on the acinar cells themselves as well as centrally.

The gut-related peptides, leptin and ghrelin, as well as influencing appetite behaviour, are also regulatory factors in the exocrine function of the pancreas. This effect is believed to occur via hypothalamic centres.

The endocrine pancreas

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are *five main types of islet cell* corresponding to different secretory components. The *beta cells* are the most common and are responsible for insulin production. The *alpha cells* produce glucagon. The *D cells* produce somatostatin, *PP cells* produce pancreatic polypeptide and *enterochromaffin cells* produce serotonin.

A number of other hormones have been identified within the endocrine pancreas including gastrin-releasing peptide, neuropeptide Y and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.

INVESTIGATION OF THE PANCREAS

Assessment of exocrine function

The assessment of pancreatic exocrine function is used in the investigation of patients with possible chronic pancreatic disease. Clinically evident fat malabsorption does not occur until there has been an 85–90% reduction in pancreatic lipase and is therefore a very late manifestation of pancreatic disease.

Direct tests of pancreatic function

These tests rely upon the analysis of a duodenal aspirate following pancreatic stimulation.

The original test involved the oral administration of a specified meal (Lundh meal). Pancreatic stimulation is now achieved by intravenous secretin and cholecystokinin.

The aspirate is assessed for pancreatic enzymes and bicarbonate production. The procedure is time-consuming and requires a meticulous technique. There is good correlation with moderate to severe pancreatic function loss, but not for mild damage. These tests are not widely available.

The measurement of peak bicarbonate secretion following secretin stimulation is also performed using an endoscopic technique for aspirate collection. This method offers similar levels of predictive accuracy as seen with the secretin-cholecystokinin stimulation test but does require a 30 min endoscopic intubation.

Non-invasive indirect tests of pancreatic function

Faecal test

- **Faecal fat estimation** (see p. 264).
- **Faecal elastase.** This pancreatic specific enzyme is not degraded in the intestine and has high concentrations within the faeces. Diminished levels may be detected in moderate as well as severe pancreatic insufficiency. This has replaced the faecal chymotrypsin test.

Oral pancreatic function tests

- **N-benzoyl-L-tyrosyl-p-aminobenzoic acid** (basis of PABA test) and **fluorescein dilaurate** are oral compounds utilized in pancreatic function tests. Both are digested by pancreatic enzymes releasing substrates which are excreted and measured in the urine. Both tests are commercially available and have good

sensitivity in moderate to severe pancreatic exocrine failure.

Clinical application of pancreatic function tests

While the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, these are very rarely used outside specialized centres. The non-invasive tests are widely available but are only highly sensitive in the detection of severe pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity and is the test of choice as a screening tool for pancreatic insufficiency.

Pancreatic imaging

Imaging (see p. 309) has a pivotal role in the investigation and management of pancreatic disease, which covers the spectrum of acute, chronic and malignant conditions.

- **A plain abdominal radiograph** may show the calcification associated with chronic pancreatitis, particularly when alcohol is the aetiology.
- **Ultrasound** of the pancreas is a useful screening investigation for inflammation and neoplasia. Views may be limited by overlying bowel gas.
- **CT scan** with contrast enhancement and following a specific pancreatic protocol remains the 'gold standard' imaging technique for the investigation of pancreatic disease.
- **MRI scanning** represents an alternative to CT. Magnetic resonance cholangiopancreatography (MRCP) gives clear definition of the pancreatic duct as well as the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.
- **Endoscopic ultrasound** is very useful for identifying distal common bile duct stones which may be the aetiology of an episode of acute pancreatitis. Endoscopic ultrasound can identify the early changes of chronic pancreatitis before these are evident on other imaging methods. There is also an increasing role for this technique to stage the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion. Endoscopic ultrasound is now considered the imaging technique of choice for investigating cystic lesions of the pancreas (see below). The technique allows fine-needle aspiration and histological sampling as well as the therapeutic option of cyst drainage. Endoscopic ultrasound is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin.
- **Endoscopic retrograde cholangiopancreatography** (ERCP) was considered the 'gold standard' for diagnosing pancreatic disease. However, with the advent of MRCP and endoscopic ultrasound, ERCP is largely restricted to therapeutic intervention.

In summary, an initial transabdominal ultrasound supplemented by CT provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductular and biliary anatomy. Endoscopic ultrasound is a useful tool for the investigation of both benign and malignant disease of the pancreas and facilitates fine-needle aspiration and biopsy of targeted lesions.

PANCREATITIS

Classification

Pancreatitis is divided into acute and chronic. By definition acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. In chronic pancreatitis there is continuing inflammation with irreversible structural changes.

In practice, the differentiation between acute and chronic pancreatitis may be difficult. Any of the causes of acute pancreatitis if untreated may result in recurrent episodes classified as acute relapsing pancreatitis. In other cases the recurrent episodes of recurrent pancreatitis may represent exacerbations of an underlying chronic process.

Acute pancreatitis

Acute pancreatitis is a syndrome of inflammation of the pancreatic gland initiated by an acute injury. The causes of acute pancreatitis are listed in Table 7.18. In the western world, gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see below). The severity of the pancreatitis may range from mild and self-limiting to extremely severe, with extensive pancreatic and peripancreatic necrosis as well as haemorrhage. In the most severe form (approximately 10% of cases), the mortality is between 40% and 50%.

Pathogenesis

The pancreatic inflammatory response is secondary to the premature and exaggerated activation of digestive enzymes within the pancreas itself. An acute rise in intracellular calcium may be the initiating mechanism, leading to early activation of trypsinogen to trypsin and impairment of trypsin degradation by chymotrypsin C. It is these activated enzymes which are responsible for cellular necrosis. In the case of gallstone-related pancreatitis it is believed that stones occlude the pancreatic drainage at the level of the ampulla leading to pancreatic ductular hypertension. Such ductular hypertension has been shown in animal models to increase cytosolic free ionized calcium. There is also evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells.

Table 7.18 Causes of pancreatitis

Acute	Chronic
Gallstones	Alcohol
Alcohol	Tropical
Infections (e.g. mumps, Coxsackie B)	Hereditary
Pancreatic tumours	Trypsinogen and inhibitory protein defects
Drugs (e.g. azathioprine, oestrogens, corticosteroids, didanosine)	Cystic fibrosis
Iatrogenic (e.g. post-surgical, post-ERCP)	Idiopathic
Hyperlipidaemias	Trauma
Miscellaneous	Hypercalcaemia
Trauma	
Scorpion bite	
Cardiac surgery	
Idiopathic	

Clinical features

Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The pain usually begins in the epigastrium accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity, the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain.

The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In severe disease, the patient has a tachycardia, hypotension and is oliguric. Abdominal examination may show widespread tenderness with guarding as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical (Cullen's sign) and flank bruising (Grey Turner's sign). In patients with a gallstone aetiology, the clinical picture may also include the features of jaundice or cholangitis.

Diagnosis

Blood tests

- **Serum amylase** is an extremely sensitive test if it is three times the upper limit of normal when measured within 24 h of the onset of pain. A number of other conditions may occasionally cause a very elevated amylase (Table 7.19). Amylase levels gradually fall back towards normal over the next 3–5 days. With a late presentation the serum amylase level may give a false-negative result.
- **Urinary amylase** levels may be diagnostic as these remain elevated over a longer period of time.
- **Serum lipase** levels are also raised in acute pancreatitis and these remain elevated for a longer period of time than those of amylase. However, overall, the accuracy of serum lipase is not significantly greater than amylase and it is technically more difficult to measure.
- **C-reactive protein level** is useful in assessing disease severity and prognosis.
- **Other baseline investigations** include a full blood count, urea and electrolytes, blood glucose, liver biochemistry, plasma calcium and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 hours and provide a basis for assessing the severity of an attack (see below).

Radiology

- An erect **chest X-ray** is mandatory to exclude gastroduodenal perforation, which also raises the serum amylase (Table 7.19). A supine abdominal film may show gallstones or pancreatic calcification.

- An **abdominal ultrasound scan** is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal common bile duct but dilated intrahepatic ducts may be present in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis as well as peripancreatic fluid collections if present. In severe pancreatitis the pancreas may be difficult to visualize because of gas-filled loops of bowel.
- **Contrast-enhanced CT scanning** is essential in all but the most mild attacks of pancreatitis. It should be performed after 72 h to assess the extent of pancreatic necrosis. CT provides very valuable prognostic information. Later, repeated CT scans can detect other complications including fluid collections, abscess formation and pseudocyst development (Fig. 7.38).
- **MRI (MRCP)** assesses the degree of pancreatic damage and identifies gallstones within the biliary tree. MRI is particularly useful to differentiate between fluid and solid inflammatory masses.
- **ERCP** is used as a treatment measure to remove bile duct stones in selected cases of gallstone-related pancreatitis (see below).

Assessment of disease severity

The majority of cases of acute pancreatitis are mild and run a short, self-limiting course. Approximately 25% run a more complicated course and in 10% this may be life-threatening. In the more severe cases, the clinical course may be marked by haemodynamic instability and multiple organ failure. The early prediction of such a severe attack allows appropriate monitoring and intensive care to be in place.

Early clinical assessment has been shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Elevations of CRP of >200 mg/L in the first 4 days have an 80% predictive value of a severe attack. Multiple factors are also used to develop scoring systems (Table 7.20). The **Ranson and Glasgow scoring systems** are based on such parameters and have been shown to have an 80% sensitivity for predicting a severe attack, although only after 48 h following presentation. The **acute physiology and chronic health evaluation (APACHE) score** has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. The APACHE scoring system is based on common physiological and laboratory values and adjusted for age as well as the presence or absence of a number of other chronic health problems (Table 7.21). This scoring system appears to have a high sensitivity as early as 24 h after onset of symptoms. There is evidence that obesity predicts the outcome from an episode of pancreatitis as the excessive adipose tissue is a substrate for activated enzyme activity. This will in turn generate an extensive inflammatory reaction. Even modest obesity (BMI between 25 and 30) has an adverse effect. This is incorporated as an adverse factor in the APACHE score (p. 897) for acute pancreatitis, and other variables have also been added.

Treatment

The initial management of acute pancreatitis is similar, whatever the cause. A multiple factor scoring system (ideally APACHE II with a modification for obesity) should be used at the end of the first 24 h after presentation to allow identification of the 25% of patients with a predicted severe attack.

Figure 7.38 (a) An abdominal CT scan with arterial phase contrast in a patient presenting with acute pancreatitis 48 h previously. The pancreas is swollen with very little uptake of contrast suggesting a severe necrotizing process. There are peri-pancreatic inflammatory changes (inf). The liver and spleen are identified for reference. **(b)** A coronal view of a CT scan in the same patient carried out in second week after presentation. There is now a large fluid collection with debris within. This is a precursor of a large pseudocyst, which extends down the left paracolic gutter into the pelvis. This has occurred as a consequence of a pancreatitis-induced ductal leak. The liver, stomach and duodenum are defined for reference. PV, portal vein; Ps, pseudocyst.

This should be repeated at 48 h to identify a further subgroup who appear to be moving into the severe category. These patients should then be managed on a high-dependency or intensive care unit. Even patients outside the severe category may require considerable supportive care.

Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access as well as a central line and urinary catheter to monitor circulating volume and renal function.

- **Nasogastric suction** prevents abdominal distension and vomitus and hence the risk of aspiration pneumonia.

Table 7.20 Severe pancreatitis – factors during the first 48 h that indicate severe pancreatitis and a poor prognosis (three or more factors present predict a severe episode)

Age	>55 years
WBC	>15 × 10 ⁹ /L
Blood glucose	>10 mmol/L
Serum urea	>16 mmol/L
Serum albumin	<30 g/L
Serum aminotransferase	>200 U/L
Serum calcium	<2 mmol/L
Serum LDH	>600 U/L
P _a O ₂	<8.0 kPa (60 mmHg)
LDH, lactate dehydrogenase.	

Table 7.21 The APACHE (Acute Physiology and Chronic Health Evaluation) II scoring system parameters

Physiological	Laboratory
Temperature	Oxygenation (P _a O ₂)
Heart rate	Arterial pH
Respiratory rate	Serum:
Mean arterial pressure	Sodium
Glasgow Coma Scale	Potassium
	Creatinine
	Haematocrit
	White blood cell count
Score 0–4 (normal–abnormal). Adjust for age and severe organ insufficiency or for immunocompromised. BMI is an additional parameter.	

- **Baseline arterial blood gases** are a key predictive factor for severity of an episode and determine the need for continuous oxygen administration.
- **Prophylactic antibiotics.** Controlled data for the use of antibiotics are available but the results are not uniform in showing benefit, particularly in showing improved mortality. There is evidence that the beta lactam imipenem reduces the incidence of infected pancreatic necrosis.
- **Analgesia requirements.** Tramadol or other opiates are the drugs of choice for immediate post-presentation pain control. Unless there is prompt resolution of pain, a patient-controlled system of administration is indicated to provide continuous and adequate pain relief. Fentanyl has been used widely for this application. There is a theoretical risk that morphine and diamorphine might exacerbate pancreatic ductular hypertension by causing sphincter of Oddi contraction and they are best avoided in acute pancreatitis.
- **Feeding.** In patients with a severe episode there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and has been replaced by enteral nutrition. In the absence of gastroparesis most patients will tolerate nasogastric administration of feed without exacerbation of pain. In those with gastroparesis or poorly tolerated nasogastric feeding (exacerbation of pain or precipitation of nausea and vomitus), post-pyloric feeding should be instituted by the endoscopic placement of a nasojejunal tube.

Table 7.22 Complications of acute pancreatitis

Systemic	Systemic inflammatory response syndrome (SIRS) Multiorgan dysfunction (MOD)
Pancreas	Pancreatic fluid collections Necrosis ± infection Pancreatic abscess Pancreatic pseudocyst (after 4–6 weeks)
Lungs	Pleural effusion ARDS – hypoxia Pneumonia
Kidney	Acute kidney injury
Gastrointestinal tract	Gastrointestinal bleeding from gastric or duodenal erosions Paralytic ileus
Hepatobiliary	Jaundice Common bile duct obstruction Portal vein thrombosis
Metabolic	Hypoglycaemia Hyperglycaemia Hypercalcaemia
Haematological	Disseminated intravascular coagulation (DIC)

- **Anticoagulation** with a low molecular weight heparin for DVT prophylaxis.

In a small proportion of patients, multiorgan failure will develop in the first few days after presentation, reflecting the extent of pancreatic necrosis. Such patients will require positive-pressure ventilation and often renal support. The mortality in this group is extremely high (in excess of 80%).

Gallstone-related pancreatitis

In patients with gallstone-related pancreatitis and associated bile duct obstruction (particularly when complicated by cholangitis), endoscopic intervention with sphincterotomy and stone extraction is the treatment of choice. In the absence of bile duct obstruction, sphincterotomy and stone extraction is only of proven benefit when the episode of pancreatitis is predicted as severe. In less severe cases of gallstone-related pancreatitis the presence of residual bile duct stones can be assessed electively by MRCP or endoscopic ultrasound in the recovery phase of the acute episode and, if present, removed at the time of ERCP. To prevent a recurrent episode of pancreatitis cholecystectomy should be carried out as soon as feasible after the acute episode has resolved.

Complications of acute pancreatitis (Table 7.22)

Within the first 7 days, the morbidity and mortality of acute pancreatitis reflect the systemic inflammatory response, which in turn results in multiple organ failure. After this initial period, the prognosis thereafter is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (>50% of the pancreas) is associated with high risk of further complicated disease, frequently requiring surgical intervention.

In this minority of patients with extensive necrosis of the pancreatic and peripancreatic tissues, superimposed infection is associated with a greatly increased risk of mortality. The established techniques of open surgical debridement are being challenged by 'minimally invasive' endoscopic necrosectomy through transgastric, laparoscopic,

and retroperitoneal routes. The aims of intervention are to control infection, evacuate devitalized tissues (that are the culture medium for invasive infection), and promotion of conditions for healing.

There is now a consensus that the best outcomes from intervention are achieved when debridement is delayed until approximately 4 weeks after the onset of pancreatitis. When the damaged area has been walled off and liquefaction has begun a pseudocyst develops. If necessary, acute sepsis can be preliminarily controlled by percutaneous drainage as a bridge to the later evacuation of the more solid elements within the necrotic tissue. Although percutaneous drainage alone has been associated with some success in the treatment of pancreatic 'abscesses', the success rate in definitively treating infected necrotic tissue without the need for debridement is limited.

Long-term outcome

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductular damage. Patients with more severe acute pancreatitis may become pancreatic insufficient both with respect to exocrine (malabsorption) and endocrine function (diabetes).

Chronic pancreatitis

Aetiology

In developed countries, alcohol is reported to be the only aetiological factor in 60–80% of cases. There is a sizeable list of other reported aetiological factors which can be categorized into toxic-metabolic, genetic, autoimmune, recurrent acute or severe acute pancreatitis, obstruction and idiopathic categories (Table 7.18).

Pathogenesis

There is increasing evidence that an increase in activated trypsin within the pancreas is a common pathway for the development of chronic pancreatitis. This may occur as a result of increased/premature activation of trypsinogen to trypsin or by impaired inactivation/clearance of the activated enzyme from the pancreas. It is believed that the increased/prolonged intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the form of plugs. These then form a nidus for calcification but are also the cause of ductal obstruction leading to ductal hypertension and further pancreatic damage (Fig. 7.39).

In the case of alcohol-related chronic pancreatitis there is evidence that alcohol impairs calcium regulation leading to increased levels. These in turn promote trypsinogen activation as well as diminishing the inactivation pathway. The observation that the vast majority of people drinking excess alcohol do not develop pancreatitis suggests that the disease process is a complex interaction of different mechanisms. It is proposed that the alcohol is only one factor which interacts with other environmental and/or genetic influences (see below).

Genetic aspects of chronic pancreatitis

A number of genetic factors have been identified which influence the process of trypsin activation and inactivation. *Cationic trypsinogen* is the major form of trypsinogen produced in the pancreas and encoded by the PRSS1 gene (Fig. 7.40). Gain of function mutations of this gene are recognized as the major factor in hereditary pancreatitis, an autosomal dominant condition with variable penetrance.

Figure 7.39 Histology of chronic pancreatitis. There is considerable loss of acini and replacement by fibrosis. Inflammatory cells are relatively inconspicuous at this late stage. Islets of Langerhans (one is arrowed) sometimes escape destruction but their loss can result in diabetes mellitus. (From Underwood JC (ed.) *General and Systematic Pathology*, 4th edn. Edinburgh: Churchill Livingstone; 2004, with permission).

Figure 7.40 Genetic factors in trypsinogen activation and trypsin inactivation. Early activation of trypsinogen to trypsin within the pancreas is crucial in the development of pancreatitis. Trypsinogen activation is promoted by cationic trypsinogen mutations (PRSS1+), active trypsin, high calcium (Ca^{2+}) and low pH. Calcium levels are regulated in part by calcium-sensing receptor (CASR) and dysregulated by ethanol (EtOH). Active trypsin degradation is facilitated by CTTC and by other active trypsin molecules, but blocked by high calcium. Active trypsin within the pancreas leads to pancreatic injury, which leads to an acute inflammatory response (AIR). AIR upregulates expression of serine protease inhibitor Kazal 1 (SPINK1), which blocks active trypsin and therefore prevents further activation of trypsinogens and limits further tissue injury. Cystic fibrosis transmembrane conductance regulator (CFTR) represents an extra-acinar cell mechanism to eliminate trypsin by flushing it out of the pancreatic duct and into the duodenum. (Adapted from Whitcomb DC 2010 *Genetic aspects of pancreatitis Annual Reviews of Medicine* 61:413–424.)

Calcium levels within the pancreas have a role in the process of activation and inactivation of trypsinogen/trypsin and are in part modulated by the *calcium sensing receptor*. Mutations coding for this receptor have been associated with pancreatitis and are believed to facilitate the damaging effects of alcohol on the pancreas.

The *serine protease inhibitor Kazal type 1* (SPINK-1) is a specific trypsin inhibitor and is co-secreted with trypsinogen by the acinar cells. Loss of function mutations of the SPINK-1

gene have been associated with the development of chronic pancreatitis and in particular as a factor in the development of tropical pancreatitis (almost certainly interacting with environmental triggers).

Chymotrypsin C is produced in trace amounts by the acinar cells and has also been shown to have a role in trypsin inactivation. Loss of function mutations of the encoding gene have been identified in patients with chronic pancreatitis.

The cystic fibrosis transmembrane conductance regulator (CFTR) is expressed on the apical surface of the acinar cells and is responsible for maintaining a high volume bicarbonate rich pancreatic secretion. This high volume secretion is responsible for flushing the activated trypsin into the duodenum. The homozygote or complex heterozygote CFTR mutations associated with the cystic fibrosis disease state are almost always manifest by perinatal/early pancreatic exocrine failure (see p. 366). Recent work has identified an increased frequency of a single CFTR mutation in patients with idiopathic chronic pancreatitis.

The identification of this genetic component to the development of chronic pancreatitis has led to speculation that in many cases the evolution of the disease is dependent upon complex interaction of gene–gene and gene–environmental factors.

Autoimmune chronic pancreatitis (ACP)

This condition is now recognised as one of the **IgG4-related disorders** which include autoimmune cholangitis, Reidel's thyroiditis, aortitis and tubulo-interstitial nephritis. In all these disorders there is a raised serum IgG4 level and pathologically there is a dense lymphoplasmacytic infiltrate with many IgG4-positive plasma cells, a mild to moderate eosinophil infiltrate and an obliterative phlebitis in some organs, e.g. pancreas. ACP is one of the few settings in which the pathogenesis of the disease may be independent of the activated trypsin pathway. The hallmark of autoimmune pancreatitis is the evidence of responsiveness to steroids. Two types have been identified. The most common variant (type 1) is seen predominantly in middle-aged men and associated with raised serum and tissue levels of IgG4. Other autoantibodies including those directed towards nuclear and smooth muscle antigens are also observed. Extrapancreatic tissue involvement is common including the biliary tree (autoimmune cholangitis see above) as well as thyroid, salivary gland, and renal. The second variant (type 2) tends to occur in early midlife with equal sex distribution and does not have the autoimmune markers described for type 1. This type is commonly seen in association with inflammatory bowel disease.

The presentation of autoimmune pancreatitis is varied particularly in type 1 in which extrapancreatic disease may predominate. Abdominal pain and weight loss are common features and jaundice may be an early symptom both secondary to bile duct obstruction by the inflamed head of pancreas as well as a manifestation of cholangitis seen in type 1 cases.

Clinical features

Pain is the most common presentation of chronic pancreatitis. It is usually epigastric and often radiates through into the back. The pattern of pain may be episodic, with short periods of severe pain, or chronic unremitting. Exacerbations of the pain may follow further alcohol excess although this is not a uniform relationship.

During periods of abdominal pain anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic unremitting symptoms. Exocrine and endocrine insufficiency may develop at any time, and

occasionally malabsorption or diabetes is the presenting feature in the absence of abdominal pain. Jaundice secondary to obstruction of the common bile duct during its course through the fibrosed head of pancreas may also occur and may be a presenting feature in a small proportion of patients.

Investigations

The extent to which investigations are required is dependent upon the clinical setting.

- **Serum amylase and lipase** levels may be elevated but in advanced disease there may not be sufficient residual acinar tissue to produce this elevation.
- **Faecal elastase** level will be abnormal in the majority of patients with moderate to severe pancreatic disease.
- **Gene mutation analysis** in selected cases in whom the aetiology is uncertain. Common mutations of the PRSS1, SPINK-1 and CFTR encoding genes are available via reference centres.
- **Transabdominal ultrasound scan** is used for initial assessment.
- **Contrast-enhanced spiral CT scan** provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct the diagnosis of chronic pancreatitis can be easily established (Fig. 7.41). This may be much more difficult when these features are not present and in particular with an atypical presentation such as with steatorrhoea alone.
- **MRI with MRCP** is increasingly utilized to define more subtle abnormalities of the pancreatic duct which may be seen in non-dilated chronic pancreatitis.
- **Endoscopic ultrasound** is used increasingly when doubt about the diagnosis remains after the above imaging or specifically for assessing complications of chronic pancreatitis including pseudocyst formation and possible development of malignancy.
- **Diagnostic ERCP** has been replaced by MRCP.

Differential diagnosis

The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy should be considered in patients with a short history and in whom there is a localized ductular abnormality. Considerable

Stone JH et al. IgG4-related disease. *N Engl J Med* 2012; 366:539–551.

Figure 7.41 Contrast-enhanced CT scan demonstrating multiple calcific densities (arrow) along the line of the main pancreatic duct in a patient with chronic pancreatitis.

difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized premalignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion and lymph node enlargement. Endoscopic ultrasound may provide the most accurate assessment of a potential mass lesion.

Treatment

In patients with alcohol-related chronic pancreatitis long-term abstinence is likely to be of benefit although this has been difficult to prove.

Abdominal pain. For short-term flare-ups of pain a combination of a non-steroidal anti-inflammatory drug and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain this may be inadequate and also risks opiate dependence.

Tricyclic antidepressants (e.g. amitriptyline) and membrane stabilizing agents (e.g. pregabalin) are used for chronic pain and reduce the need for opiates. Coeliac axis nerve block may produce good pain relief but is unreliable in its extent and duration of action. In the majority of patients some spontaneous improvement in pain control occurs with time. After a 6–10-year period, some 60% of patients will become pain-free. For patients with recurrent severe or debilitating chronic pain, both endoscopic and surgical intervention has been used but with limited success. The endoscopic approach has centred upon improving duct drainage by removing intraductal stones and repeated stenting to maintain duct patency. Extracorporeal shock wave lithotripsy has been used to fragment stones within the head of pancreas. Surgical intervention usually involves a duct drainage procedure combined with partial resection of the diseased head of pancreas. Improved symptom control following surgical intervention as compared with the endoscopic approach has been demonstrated. However, it is reasonable to attempt endoscopic therapy as a first measure.

Steatorrhoea. The steatorrhoea associated with pancreatic insufficiency may be high, with up to 30 mmol of fat lost per 24 h. This will usually improve with pancreatic enzymes supplements. Current preparations are presented in the form of microspheres which reduce the problems of acid degradation in the stomach. An acid suppressor (H_2 -receptor antagonist or proton pump inhibitor) is also given. Despite this, a proportion of patients continue to malabsorb, usually reflecting the inadequate mixing of the pancreatic supplements with the food as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production. There is no justification to reduce fat intake below the recommended levels of a normal diet as this will contribute to malnutrition seen in patients with chronic pancreatitis.
